ORIGINAL LECTURES.

FREQUENT MISCARRIAGE; ITS PATHOLOGY AND TREATMENT.

A Clinical Lecture delivered at the Long Island College Hospital,

BY A. J. C. SKENE, M.D.,

PROFESSOR OF GYNECOLOGY AND VISITING PHYSICIAN TO THE HOSPITAL.

(Reported by Edward Develin, M.D.)

GENTLEMEN: To-day I intend to call your attention to the subject of frequent miscarriage; its pathology and treatment, illustrating my remarks upon this most important branch with such cases as have presented themselves here to-day for treatment.

Case I.—The patient now before you is thirty-five years of age, and has been married nineteen years. She has had no children, but has had ten miscarriages, the last one occurring a year and a half ago. Menstruation is now irregular. Our duty is to ascertain the cause of these frequent miscarriages; and in this case I have every reason to believe that it is due to the general condition of the patient. I find nothing abnormal about the vaginal portion of the uterus or the vagina itself; neither does the body of the uterus appear to be diseased or deformed.

Whenever we see this disposition to miscarry, not due to malpractice by the patient or an abortionist, I mean when they arise from natural causes, we are always sure of one thing, and that is: that there is some disease of the uterus or some specific constitutional disease. In such cases I am always suspicious of syphilis. Frequent miscarrying points strongly to constitutional disease, and that is the reason why I have just asked the patient a few questions in order that I may ascertain if she has had any evidences of syphilis. I rather think she has; I had an opportunity of seeing her before I presented her to you, and her skin looks somewhat like that of one who might be syphilitic; at all events, it lies between this constitutional condition and disease of the uterus, and as the uterus is all right we may exclude that cause.

We read about the habit of miscarrying, and in this case we have had ten miscarriages, which suggests that it has become a habit; but I hardly believe the habit is so easily established as the literature upon this subject would lead us to believe. I think in the cases which habitually occur there is some disease of the uterus, such as laceration of the cervix, bilateral and high up. In these cases pregnancy seldom occurs, and when it does a miscarriage is the result usually.

Now from the history of this case we learn that she has no marked disease of the uterus. Having menstruated irregularly, she may have some corporeal endometritis; it cannot be marked, however, or she would not have become pregnant. I am, therefore, the more inclined to think that the difficulty is syphilitic. If this be our suspicion, and the evidence given by the patient is not sufficient for a diagnosis, our inquiries are then directed to the husband, and the chances are that you would be likely to find the cause in him.

Now these cases respond very well to the anti-syphilitic treatment, and in time a living child may be borne. It is a curious fact that this disease is self-limited to a great extent, at least, in transmission; and hence in time these miscarriages are stopped and a family is raised. In relation to this matter, one of the most important observations was made by Dr. Reade, and set forth in a paper which he read before the Kings County Medical Society. It was an elaborate paper showing that the longer the time that elapsed from the contraction of the disease until the fecundation of the ovum, the less chance was there of the transmission of this syphilitic taint. In those who have the misfortune to conceive soon after an attack of syphilis, the ovum dies in utero; at the next conception the ovum may perhaps be carried a little longer, and so on until finally a child is born showing little of the syphilitic affection. Dr. Reade also stated that the greater the lapse of time after the birth of the child, until the external manifestations of the disease, the more readily did it respond to treatment. These are important points to bear in mind.

In this case I shall take it for granted that there is some specific difficulty, and shall therefore direct her to be placed upon alterative treatment.

Now let me suppose a case: A lady has had a number of miscarriages and has been treated by her family physician, and he has failed to carry her along to the end of gestation. After a time she begins to lose faith in his treatment, and calls in some eminent physician, and he fails also; finally a third medical man is called in, and he understanding the case, as in like manner did the previous gentlemen, continues the anti-syphilitic treatment and she finally has a living child. Now this gives the last doctor a reputation at once, and yet he did not make it altogether by his skill as a physician, but simply because the transmission of the specific taint was nearing its close; and hence she was becoming more competent to carry the child the full time. Such a case came under my observation about ten years ago, and I attended the lady during her confinement, and at once placed the child upon specific treatment. I believe the child is living to this present day. The result of this was that I have since had several such cases, but sometimes I fail, just as these other gentlemen did, in recent cases. You can thus see how important it is to bear in mind these points, and by this means hold out hopes to your patient of her ultimately raising a family.

Case II.—This patient is thirty-five years of age; has been married ten years; has had three children and three miscarriages; one miscarriage occurring at three months, one at four months, and one about seven months. I supposed that these miscarriages resulted from laceration of the cervix uteri, as they are very prone to occur from that cause, but I am now informed that since her miscarriages she has borne a living child, therefore the miscarriages must be due to some other cause.

Upon examination I find the uterus to be, as near as I can judge, about three and a quarter inches in length, from the junction of the vagina and cervix. I show you here a double laceration of the cervix, extending up to the vaginal insertion to which we just now referred. The uterus is retroverted, and this displacement, taken together with the laceration of the cervix, is sufficient to account for her miscarriages. I have already spoken of the relation of lacerations of the cervix uteri to miscarriages, and I need only say that retroversion, when well marked, is equally capable of arresting gestation. Fortunately, we can remove this cause of abortion by restoring the uterus to its normal position, and retaining it there by a pessary until the uterus is sufficiently enlarged to rise out of the true pelvis.

A pessary was introduced some time ago for the purpose of sustaining the uterus in position. I drew your attention to the position of this pessary previous to its removal, namely, that it was projecting from the introitus. This pessary was introduced in a New York hospital, and is the retroversion pessary of Dr. Thomas, one that I was in the habit of using quite frequently, but I object to the shape of this one; the posterior bar is made too large, and the whole instrument has too much of a wedge-shape. In this pessary the wedge comes almost to a sharp point. While I believe in the wedge-shape pessary introduced by Dr. Albert Smith, of Philadelphia, this one is too sharply tapering. This broad bar which you see here, and upon which the pressure is brought to bear, has pushed the instrument down to the introitus. Now I know that this pessary has been out of position for weeks, although I have never seen the patient until this hour, for I find upon the lower portion of the pessary an incrustation of the salts of urine, showing that the patient has been urinating upon it. This could not occur if the pessary was in proper position unless she had laceration of the urethra. So, then, this instrument, while it has done much good, is not wide enough to sustain the uterus and retain the position in which it was placed in the vagina. That is one of the reasons why I shall give it up. Now do not understand me to condemn this shape of pessary by any means, for it certainly has its advantages. The idea in its design by Dr. Thomas was good, but it has been spoiled in making. Though an instrument may be sent to the instrument maker with full instructions as to its mechanism, the exact shape, and its uses, he will oftentimes fail to follow your directions explicitly. This is, then, no fault of the gentleman who has devised the instrument, although in many cases it leads to an unfair criticism of the instrument by those who have been unfortunate enough to purchase one of these badly made articles. This one has too much of a wedge-shape and is too long, and hence is constantly slipping down. The reason the posterior bar is made large is to prevent its being imbedded in the vaginal walls. This instrument was designed for the purpose of keeping the uterus in position after it has been replaced there, and it will do this if the instrument be not too narrow. There are, however, as I have previously mentioned, two methods of restoring the uterus to its normal position—we may restore the uterus partially and gradually secure an improved position of the organ, until finally it resumes its normal relations with surrounding parts; or we may restore the uterus at once and keep it in place. The advantage of this retroversion pessary, when properly made, is that you can make more pressure, and compel the organ to stay in position, better than any other instrument that I have used. I however prefer the gradual method rather than the rapid method. There is here another point I would call your attention to—this pessary has done this woman good service although it is somewhat too long. She states that it has afforded her great relief, and asks that she be permitted to wear it again. So when a patient feels so much comfort from the use of any instrument, you may know that it is effecting its object; by this you can be guided in your future treatment of the case. We can improve upon this instrument by using a wider one, which will accomplish the object and at the same time not annoy the patient by projecting from the vulva.

Case III.—This patient is thirty-seven years of age, and has been married nine years; she has two children living, and has had three miscarriages, the last one occurring ten days ago. She has had amenorrhœa for the past three or four months, and, of course, had metrorrhagia when she miscarried; the flow, she informs me, stopped yesterday.

The case is interesting because of the uterine hemorrhage which is so liable to continue after miscarriage, especially when the emptying of the uterus has not been complete. I think the rule is that in a miscarriage, if the ovum be cast off complete, that will be the end of it, if you treat your patient with rest and care. But if the ovum becomes broken, and part of it remains, no matter how small it may be, there is likely to be a little oozing for a long time; perhaps it has been so in this case, and had this hemorrhage continued, we would have emptied the uterus, and endeavored to relieve her. On examination, I find the uterus is larger than normal, and it is soft—it is not well contracted.

In this case we will advise rest, a little ergot, and the application of the warm-water douche—this will induce the uterus to return to its normal dimensions.

Case IV.—Here is, I believe, a most singular case, although I have not had time fully to look it over. The patient is married, and is aged twenty-five years. She informs me that for the past three months her menses have been very irregular, and at times hemorrhage occurs. She gives no very clear history, but there is a peculiarity about this hemorrhage which I especially desire you to notice; it is this, that when she lies down she suffers more from the hemorrhage, but when she assumes the erect position the hemorrhage ceases. This is somewhat peculiar, and is almost pathognomonic of one condition. I will, however, examine the uterus before I commit myself to a diagnosis. On examination, I find the uterus to be about five inches in length, as near as I can measure; I find it is perfectly uniform in size; it is pear-shaped, and differs only from the normal non-pregnant uterus in that it is enlarged. I also find it to be quite elastic to the touch; it does not present that dense structure so perceptible in fibroids; here it has a soft, doughy feeling. Her menstruation for the last three months has been so irregular that the probability is that she has not menstruated at all, but has been suffering from metrorrhagia and that peculiar hemorrhage when she lies down.

Now, without dwelling on a case of this kind, I will say that I believe it is due to a retarded or delayed miscarriage. I believe that she has been pregnant,

and that the ovum has died without being expelled; perhaps a part of the ovum may be attached and retain its vitality. Now, the contents of the uterus when the patient assumes the erect position act as a valve at the os internum, but when she lies down it falls away from the os and a hemorrhage takes place, the blood accumulating in the uterus while she is standing or walking about. I have seen a sufficient number of these cases to be almost positive in my diagnosis, and in addition I have the advantage in that Dr. Cushing has examined the patient and has come to the same conclusion. I know of no other condition in which that occurs, although there is a case reported by Dr. J. Marion Sims in which somewhat similar symptoms were found, resulting from a polypus or something of that nature. He, however, does not mention anything relating to the effect of the erect or the recumbent position upon the hemorrhage.

In one case that came under my care the ovum died at four months, and at the seventh month I removed it; the patient had hemorrhage precisely in the same manner as this one. At the time I emptied the uterus the temperature was 105°, and the pulse one hundred and three. As soon as the uterus was emptied the temperature came down at once, and the patient is alive and well to-day. Dr. C. H. Smith brought to my notice a case of this kind, in which the patient was often obliged to sit up in bed during the night to stop the bleeding. I desire you to bear in mind this peculiar point in the clinical history of these cases, it is a valuable and important lesson. We will see what the uterus contains, and report to you the result.

ORIGINAL ARTICLES.

A CONTRIBUTION TO THE HISTORY OF LIGATION OF THE COMMON FEMORAL ARTERY.[1]

BY L. McLANE TIFFANY, M.A., M.D.,
PROFESSOR OF SURGERY IN THE UNIVERSITY OF MARYLAND.

LAST summer it was my fortune to have to deal with a large aneurism of the femoral, extending upwards to within two or three inches of Poupart's ligament, and while pressure, with rest, was being tried to effect a cure, I very naturally turned to the recorded experience of others, with the intention of tying the common femoral artery, if pressure failed. So the first author my hand lighted upon said that, while he preferred to tie the external iliac rather than the common femoral for aneurism high in the thigh, yet he was not prepared to condemn a further trial of the common femoral. My next author was more favorable, for by him the common femoral was preferred to the external iliac. My third author condemned the operation unhesitatingly as not fit to be done, and from the state of depression in which I now was, nothing aroused me until I put my eye on author No. 4, who says that it is the duty of the surgeon to tie the common femoral in preference to the external iliac. I therefore, with care, returned my four advisers to their shelves, and tied, according to my original intention, the common femoral of my patient, who recovered with rapidity both from his aneurism and his doctor.

CASE.—J. W., aged fifty-eight years, male, mulatto, tall, rather spare, noticed in March, 1883, a lump in the left groin. When first discovered, the enlargement was about, so he described it, the size of a pullet's egg, probably an inch and a half by two and one-half inches. During the month of May, increase was rapid. June 17 of the same year, I first saw the patient. The enlargement at that time was oval, extending from within two and one-half inches of Poupart's ligament to within five inches of the upper border of the patella. The circumference of the affected thigh, the left, measured over the most prominent portion of the tumor, exceeded by five inches the circumference of the right taken at a corresponding place. There was decided œdema of the limb below the tumor; pulsation was distensile and marked; pressure upon the common femoral abolished pulsation, but did not bring about entire subsidence of the swelling; aneurismal bruit distinct; pain great; the most comfortable position being with the limb semiflexed and everted. The continuance of this position for a certain time had caused an incipient bedsore upon the outer side of the foot and little toe. There was no history of syphilis. Aneurism of superficial femoral was evident. Compression was commenced June 26, with two horseshoe tourniquets, having small pads so adjusted as to press upon the femoral between Poupart's ligaments and the aneurism; the tourniquets were, of course, tightened and relaxed alternately. Morphine was given q. s. At the end of ten days but little good had resulted from the use of tourniquets, although complete as well as partial stoppage of the blood-current had been brought about at different times. Veratrum viride was given also, and the pulse by its means kept down.

July 14 I tied the common femoral half an inch below Poupart's ligament with silk. Pulsation was easily felt through the skin, and this, together with subcutaneous connective tissue, being divided, the artery came into view. By pressing the vessel from one side to the other, I was able to feel that no large branch came from it within half an inch or an inch of the place to be tied. One very small vessel was given off just where exposed, so this was tied in addition to the main trunk. Pulsation in the aneurism at once ceased, and did not recur. One end of the ligature was left hanging from the wound; iodoform and absorbent cotton constituted the dressing. Convalescence was without interruption, and calls for no comment. The external border of the foot and little toe, which were denuded before the operation by pressure, became the site of a troublesome ulceration, and healed but slowly, the toe sloughing off. The aneurism consolidated, became very gradually smaller, and was, when last seen, represented by a firm lump, causing no inconvenience.

Fortified by a successful case, I was of course prepared to criticise the opinions of others, and I venture to say that there are few operations in regard to which so many divergent opinions are expressed by competent men. From unqualified condemnation

[1] Read before the American Surgical Association April 30, 1884.

to unqualified praise there is an easy gradation of advice and opinion not only from those who have neither performed nor seen the operation, which need cause no surprise, but singularly enough even from those who have themselves operated. The Irish surgeons approve of the operation, notably Porter, who gives three cases with recovery, and so well describes the anatomy of the locality, etc., as to justify the expression occasionally used—"Porter's operation."[1] English surgeons, with scarcely an exception, do not favor the operation. Macnamara favors the operation and reports cured cases[2] including one of his own. Erichsen is strong in opposition[3]. Holmes[4] approves the measure rather than to tie the external iliac, while Bryant[5] requires more experience before recommending it. Pemberton[6] is the most pronounced in favor of the measure of all surgeons who have written. American surgeons, with but one brilliant exception consider the operation injudicious and inexpedient. Mott[7] is the exception, and he says, "some surgeons have doubted the propriety of tying the artery between the giving off of the profunda and the origin of the epigastric. We have, however, several times put a ligature here, and in every instance with success." This is very strong endorsement.

A foot-note on the same page states that since the above was written, he—Mott—has again tied the common femoral with success. It is greatly to be regretted that the matter is left in so crude a condition; no particulars are given about age, sex, cause, manner of operating, etc. The only seeming excuse for such omissions in so careful a writer being, that there could be in Mott's mind no doubt as to the propriety of the procedure and discussion therefore was needless.

Continental surgeons are generally not in favor of the operation. The most exhaustive article with which I am acquainted is by Rabe,[8] with an analysis of one hundred and seventy-eight ligations of the common femoral for all causes. In this elaborate summary of our knowledge up to the time of its publication, 1875, a comparison is instituted between ligations of the large arteries of the lower extremity in regard to secondary hemorrhage and gangrene as affecting the general mortality, the outcome being not favorable for the common femoral ligation. Unfortunately, the Irish cases have escaped due credit, Porter[9] being omitted, as also Smyly. Laugier[10] is entirely omitted with two successful cases. An unsuccessful case by Gelston[11] is likewise omitted.

For aneurism, the vessel under discussion has been tied but a very few times, the enormous majority of ligations being for hemorrhage following traumatism, and Rabe, after collecting and analyzing 540 ligations of the superficial femoral, 178 of the common femoral, 207 of the external iliac, and 27 of the popliteal, for all causes, makes use of the following language: "It is necessary to add that neither of these ligations, in case of traumatic hemorrhage, performed at a distance, prevents more surely the one than the other the recurrence of hemorrhage," a sentence which conveys the highest compliment to the teachings and opinions of Guthrie, that most competent surgeon. Laugier's cases, already referred to, were both wounds of the artery, in which ligatures were applied above and below the seat of injury. Both patients recovered. Rabe disapproves of tying the common femoral, advising that either the superficial femoral or the external iliac should be secured. Turretta,[1] in Italy, after the recovery of a traumatic case in which, having tied the common femoral above the wound, hemorrhage occurred, and he tied the external iliac, comes to the same conclusion as Rabe. If he had tied the vessel above and below the wound, his conclusion, as well as his practice, would have been better.

In the History of the War, Part 3, Surg. Vol., p. 789, will be found Table CXLI., being a summary of 374 ligations of the femoral artery. A certain number of these refer to the common femoral. I append a brief history of each case, for which I am indebted to the extreme courtesy and kindness of the officials of the Library of the Surgeon-General's Office, not only in affording me every possible facility to investigate, but also in making transcripts of documents beyond my reach.

For traumatic aneurism there is recorded one case, No. XIII., of the table referred to.

Injury to femoral in August, 1864; no primary hemorrhage; aneurismal sac formed; ligation of femoral above profunda, September 1, 1864; ligature separated ninth day; recovery.

For secondary hemorrhage after amputation there are four cases, with two recoveries.

CASE XVII.—Fracture of knee-joint, October 27, 1864; amputation, thigh, October 28; *gangrene* in stump three weeks after operation; secondary hemorrhage on third day; femoral ligated just above profunda; recovery.

CASE XXI.—Fracture of knee-joint, March 31, 1865; amputation, thigh, same day; hemorrhage from profunda, April 4; same day ligation of femoral above profunda; recovery.

CASE CCLXV.—Wound of thigh, August 29, 1862; amputation, same day; hemorrhages, September 5, 6, 7; ligation of femoral above profunda, September 7; hemorrhage recurred September 8; died September 12, 1862.

CASE CCCLXV.—Fracture of femur, May 5, 1864; amputation of thigh, June 2; hemorrhage, June 5, and femoral artery ligated above profunda on the same day; died, June 5, of exhaustion.

For hemorrhage secondary after a wound there are recorded thirteen instances, two of which recovered. This list includes two cases in which the vessel was ligated three-quarters of an inch below Poupart's ligament, and, therefore, presumptively above the profunda, although not stated in so many words.

CASE XXIV.—Wound of thigh, May 16, 1864; secondary hemorrhage, and femoral ligated above profunda, May 29; recovered.

CASE LXXXIX.—Wound of thigh, April 2, 1865; hemorrhage from branch of femoral, April 11; ligation of femoral above profunda in Scarpa's space, April 12; recovery.

CASE CXL.—Wound of thigh, femoral injured, April 1, 1865; April 10, hemorrhage from femoral and descending branch of profunda; femoral ligated on the same day above profunda; *gangrene* of entire limb; died April 19, 1865.

CASE CLXXXIII.—Fracture of femur, May 28, 1864; hemorrhage from profunda, June 19; ligation on same day of femoral just below Poupart's ligament, and above probable origin of profunda; hemorrhage recurred June 20 and 21; wound plugged with persulphate of iron; died, June 25, of exhaustion, following secondary hemorrhage.

CASE CXC.—Wound of thigh, June 1, 1864; June 8, hemorrhage from deep branches of profunda; profunda ligated one inch below origin; bleeding continuing, the femoral was ligated two inches above the profunda; death, June 15.

CASE CCXI.—Wound of thigh, March 16, 1865; hemorrhage, April 3, from profunda; profunda ligated same day; April 5, femoral ligated just below Poupart's ligament; *gangrene;* death, April 8, 1865, of gangrene.

CASE CCXIII.—Wound of thigh, May 15, 1864; *gangrene* of wounded parts; hemorrhage, May 28, from profunda; femoral ligated same day, one-half inch above profunda; died of gangrene, June 2, 1864.

CASE CCXVII.—Wound of thigh, May 10, 1864; hemorrhage from profunda, May 19; ligation of profunda, same day; hemorrhage recurred May 22; femoral ligated above profunda, May 22; hemorrhage recurred thirty-six hours after—arrested by compression; died May 26, 1864.

CASE CCXIX.—Wound of thigh, June 9, 1864, ball lodging close to femoral; hemorrhage from femoral, July 5; ligation of femoral above profunda on same day; ligature came away July 11; hemorrhage recurred at four different times; died of chronic diarrhœa, September 25, 1864.

CASE CCLXIX.—Wound of thigh, May 18, 1863; great primary hemorrhage (probably ceased spontaneously); June 3, hemorrhage from profunda; ligation of femoral above profunda same day; hemorrhage recurred from branches of internal iliac; death, June 10, 1863, from exhaustion, following hemorrhage.

CASE CCCVII.—Wound of hip, May 12, 1864; hemorrhage, May 28 and 29, from branch of profunda or pudic artery; femoral ligated May 29, three-fourths of an inch below Poupart's ligament; hemorrhage recurred fifty-six hours after operation; death, June 2, from secondary hemorrhage.

CASE CCCXXXIV.—Wound of thigh, May 18, 1864; hemorrhage from circumflex, May 30; June 2, femoral ligated three-fourths of an inch below Poupart's ligament; hemorrhage recurred three hours after operation; died from exhaustion, June 5, 1864.

CASE CCCLIII.—Fracture of femur, May 10, 1864; hemorrhage from femoral, June 7; femoral ligated above profunda, June 9; died, June 17, 1864.

There are certain other cases of the table in which it is likely that the common femoral was tied, but in the absence of specific statement to that effect, and in the absence of knowledge concerning the exact site of the ligature, they must be omitted here.

Gangrene is recorded four times—Cases XXVII., CXL., CCXI., CCXIII.—but no distinction is made between the variety resulting from obstruction to the circulation and that resulting from hospital infection. As the seat of hemorrhage is but rarely stated, whether from the proximal or distal side of the wound, analysis of the cases is not possible. From the large mortality, however, it may be safely inferred that to tie the common femoral for a distal wound, rather than to tie both ends of the vessel in the wound, is to be avoided if possible, for it exposes the patient to needless risk.

As germane to the subject of bleeding from the lower end of a wounded artery, Gelston's[1] case may be cited: The vessel was tied in Porter's canal, July 2d, for aneurism; secondary hemorrhage July 17th, and ligation of external iliac; bleeding occurred from the distal end of the old wound July 19th; the wound was plugged; bleeding recurred several times; death August 1st. I cannot avoid thinking that for traumatic cause this vessel (common femoral), perhaps, has been tied in consequence of its extremely superficial position, and the facility with which the operation is done, as compared with the difficulty of finding a bleeding artery and putting a string on it in a sloughy or deep wound.

For causes not traumatic, elephantiasis, and aneurism, how about tying the common femoral? Rabe gives ten cases in which the vessel was secured for the former cause, elephantiasis, with one death and nine recoveries. The same author gives twelve cases of ligation for spontaneous aneurism, with six recoveries and a like number of deaths; but cases by Porter,[2] Smyly,[3] Lister,[4] Gelston,[5] and several cases by Mott, probably, are not to be found in his list. Looking at the unfavorable cases, it appears that death is generally brought about by hemorrhage, whether from the proximal or distal end of the artery, is, however, but exceptionally stated. I find an explanation for this secondary hemorrhage in the variable anatomy of the vessel, sometimes being extremely short, sometimes long, according as the profunda commences close to, or at a distance from, Poupart's ligament. The length usually ascribed to the common femoral is from one to two inches, probably more often one than two. A fair average would be one and a quarter inch; and, inasmuch as the separation of a ligature from a tied artery is generally attended with hemorrhage if a large branch be close at hand, the amount of working space afforded the surgeon does not appear excessive, and might be contracted; it must, however, be remembered that variation in origin is not the prerogative of the deep femoral only, but that the epigastric and circumflex ilii are given off by the external iliac at a variable distance from Poupart's ligament.

When, therefore, the common femoral is under consideration with a view to ligation, and the origin of the profunda discussed, due regard must be paid to the possible extent of external iliac without branches

[1] Loc. cit. [2] Loc. cit. [3] Loc. cit.
[4] Address before Brit. Med. Assoc. 1871. [5] Loc. cit.

above Poupart's ligament; and, should the commencement of the profunda be exposed, the operator will apply the ligature above or below, or tie both vessels according as his judgment may direct after careful examination. Published cases prove that these considerations are not theoretical. Pemberton tied, as he thought, the common femoral, and the patient recovered, death occurring a certain time afterwards from causes foreign to the operation. He was able to examine the parts, and found that he had really tied the superficial femoral, for the profunda arose as high as Poupart's ligament.

Collis, quoted by Macnamara, thought he tied the common femoral; death took place from secondary hemorrhage, and the profunda was found on inspection to be given off immediately above the ligature. The string had been put around the superficial femoral.

In the table already referred to (Medical and Surgical History of War), is a somewhat similar case, the particulars of which are as follows:

Case CXLVIII.—Wound of thigh and injury to femoral, May 31, 1862; hemorrhage June 10th; femoral ligated on the same day, as was supposed, above the profunda; but the profunda being given off unusually high, was also tied; hemorrhage from profunda recurred June 17th, profunda religated same day; died from exhaustion two hours after operation.

Pemberton, in a second case, and Lister have successfully tied with antiseptic catgut; it is possible that this method of tying the artery, under consideration, may reduce the mortality. The common femoral being covered by but skin with connective tissue, can be readily exposed, can be examined by touch and sight, and the presence of a neighboring large branch recognized. Should the limb be œdematous as high as the groin, the application of a horse-shoe tourniquet with the pad over the artery for a short time will render the vessel again superficial. Recourse was had to this expedient in my own case. The fact that the crural sheath encloses a funnel-shaped space much larger than the contained vessels can fill, permits a free examination for the profunda. It will be probably wise, in view of the shape of the crural sheath, to open it freely for another reason, lest drainage occur backwards toward the pelvis rather than outwards. From the study of recorded cases I am led to the following conclusions:

1st. Ligation of common femoral in continuity for distal wound is attended with great mortality, and should not be substituted for the application of ligatures to an artery above and below the point wounded.

2d. Ligation of common femoral for elephantiasis or aneurism, is proper.

3d. The crural sheath should be freely opened and the vessel carefully examined for the origin of the profunda and epigastric, the ligature not to be tied within a half or three-quarters of an inch of either.

4th. Half or three-quarters of an inch below Poupart's ligament will probably be the most favorable locality for the ligature.

5th. The presence of a small branch near the seat of ligature does not contraindicate the operation; such branch should be also tied.

TRAUMATIC RUPTURE OF RETINA AND CHOROID BY A PLUSH BALL.[1]

By CHARLES SHAFFNER, M.D.,
Assistant Surgeon to the Eye and Ear Department of the Philadelphia Dispensary.

On September 11, 1883, V. H., a school-boy, ten years old, applied for treatment at the Philadelphia Eye and Ear Dispensary, stating that he had received a blow over the left eye in play from a plush ball at the hands of a playmate two days before. This brought on moderate pain for a half hour and caused him to cry, as the mother thinks, more from fright than from severe pain. She applied cold water to the eye, and this was all the treatment he had until he fell into my hands. He soon noticed that he had lost almost all his sight in his left eye, and his mother's anxiety on account of this was the direct cause of his seeking treatment.

At his first visit the right eye $= \frac{18}{xx}$; accommodation = J. 1 at 3″ to 25″; H. 1.5 D. Left eye $= \frac{4}{cc}$; accommodation = J. 1 at 2″ to 5″; M. 6 D. Right eye, ophthalmoscopic examination showed nothing abnormal except that the optic papilla was rather pale, and had a crescent to the outer side, amounting to one-sixth of its diameter.

Left eye showed a pale optic papilla, oval in shape; axis 90°, with a porus opticus equal to one-sixth of disk, and with a crescent equal to one-tenth of a diameter. Outwards from the disk were seen three vertical white lines (ruptures of the choroid) the first of which was about a half a diameter away from the disk, and extending about one-fourth an inch in a vertical direction, as everything is magnified by the lens of the eye; lower down was a small spot of choroiditis; outwards from this rupture was another, not more than one-third the size of the first, and about a fourth of a diameter further outwards, also vertical in its direction, and showing white sclerotic in its depth. About the region of the macula lutea was another and very striking rupture, much larger, whiter, and bifid above, showing a very white background.

A slight fresh clot was hanging to its inner edge and floating in the vitreous in front of the rupture. The retina was generally congested, and its vessels much enlarged. The conjunctivæ were not congested, cornea was normal. Pupil was considerably dilated and did not react to light (no atropia had yet been used). The lens was in place and uninvolved.

Treatment was rest in the house in a moderately dark room, an eye-shade and a solution of atropiæ sulph. gr. j to ℥j in left eye once daily.

About September 22d I examined him carefully again, and found right eye vision $= \frac{15}{xx}$; H. 1.5 D. Left eye vision $= \frac{15}{cc}$(?); H. 2.25 D, or return to hypermetropia. A change from myopia, showing swell-

[1] Read before the Philadelphia Ophthalmic and Aural Book Club Association, March 17, 1884.

ing of the disk. The largest rupture was seen to be half a diameter in width, and several diameters in length. The smaller ruptures were surrounded with hemorrhages. The spot of choroiditis did not appear. The edges of the disk were indistinct and cottony, showing that neuritis had set in. Choroid was congested and its circulation rather plainly seen. Retinal vessels were dilated. The pupil was still much dilated, although very little atropia had been used, the case having been left almost entirely to nature.

September 29th, right eye vision $= \frac{15}{XX}$. Left eye vision $= \frac{15}{XL}$. The largest rupture appeared with a black border, otherwise the same as before, while vision was much improved. No marked change of tension, but it might be a little diminished.

Left eye for near vision has come up to reading J. 6 at 3″ to 10″.

A CONTRIBUTION TO THE STUDY OF THE ETIOLOGY OF MALARIA,

BASED UPON OBSERVATIONS COVERING A PERIOD OF NINE MONTHS, AT FORT SILL, INDIAN TERRITORY.

BY RICHARD COLE NEWTON, M.D.,
ASSISTANT SURGEON, U. S. ARMY.

How much real advance has been made in establishing the true nature of the cause, or causes, of malarial diseases since the days when Watson lectured on this subject, the reader can judge by turning to the works of that eminent teacher. To the writer, after a careful survey of the field—so much of it, at least, as is accessible to him—it appears that no material addition has been made to the common stock of knowledge from Dr. Watson's time to the present. Furthermore, certain writers and lecturers have of late boldly denied the assumption of Lancisi (which the majority have always accepted) of the existence of a specific malarial poison; while others prefer to take the fashionable position of agnostics.[1]

Even "the enthusiastic Tommasi Crudeli"[2] is quoted in the *Sanitary Engineer*[3] as saying, "Unfortunately, malaria may be produced in the most diverse soils, and that which perfectly succeeds in abolishing it in one place, may have no effect in another. . . . As yet we are working blindly. Sometimes we obtain good results; sometimes it seems as if we made matters worse. We need careful study of the *natural history*[4] of malaria, of the effect upon it of change of character or condition of soils," etc. It would seem from this that this well-known observer must have lost faith in his own alleged discoveries, or that, at any rate, he finds the "bacillus malariæ" very unmanageable.

The only paper written in defence of the specific nature of the malarial poison that I have seen very recently is a short article by Dr. D. Parker, of Texas,[1] which takes well-chosen ground in favor of the usually accepted theory.[2]

Dr. Sternberg's recently expressed hope—that the true cause of malaria will soon be demonstrated,[3] can but be the hope of every educated man, and a source of encouragement to every physician whose practice obliges him to combat this stealthy enemy from one year's end to another—with the probability that he himself will fall a victim to it at last.

The object of this paper is not to divulge anything new or startling, but simply to call attention to some facts which the writer has carefully verified, and which he believes have an important bearing upon the question of the specific nature of the malarial miasm.

The writer became Post-Surgeon in this Post (Fort Sill, Ind. Ty.) in the latter part of February, 1883, and was relieved from this duty November 20, 1883. During this period (about nine months) he attended "sick call" himself (with less than two dozen exceptions), and took entire charge of the cases in the hospital. He, therefore, is certain that all the cases diagnosticated as malarious received anti-periodic treatment (generally preceded by a mercurial purge), and believes that the diagnoses were correctly made.

The surroundings of this Post do not seem at first sight unsalubrious; but an inspection of the soil shows that it contains much clay. Watson[4] and Hertz[5] have pointed out that malaria is apt to arise from clayey soils—presumably from their imperviousness. After each rain-fall here, the water remains above ground with remarkable persistency. Moreover, owing to the comparatively flat landscape, the natural drainage is bad.[6]

Sir J. Fayrer says, "that much is attributed to climate which is more properly chargeable to defective hygiene and careless mode of living."[7] Without doubt, the hygiene of this fort is execrable, owing to the clayey soil and rank vegetation, and to the disregard of every hygienic law evinced by the builders of the barracks. These are all built of limestone—a porous, hygroscopic rock. The men's quarters (with which alone this article has to do) are of simple construction, without cellars. The floor is about three feet from the ground. The air, however, may circulate underneath, through small apertures left in the wall. There is only one wall (eighteen inches thick), roughly plastered on its inner side. There are no ceilings to the barracks, and each soldier has practically over eleven hundred cubic feet of air-space. All the barracks for the men are substantially similar.

The accompanying figure will show the disposition of these buildings as regards the creek, from which our water supply comes, and the points of

---

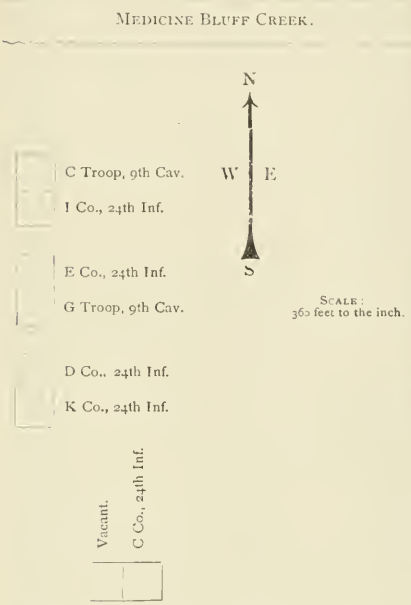
[7] Croonian Lecture, British Medical Journal, March 25, 1882.

the compass. Each building is one hundred and eighty-six feet long, and is divided equally by a



transverse partition; each half accommodating one company of soldiers. The distance from the shore of the creek to the northern end of C Troop's, 9th Cavalry, quarters is five hundred and forty feet. A passage-way of about twenty feet separates the three buildings, which run north and south, from each other. Nearly a hundred feet further south is the barrack of C Company, 24th Infantry. Medicine Bluff Creek[1] is a stream of varying volume; the water has always more or less vegetable matter suspended in it. When the stream is swollen it widely overflows its banks, and, subsiding, deposits great quantities of dead leaves, grass, etc., in varying stages of decay, along the banks, and even in the forks of trees and tops of bushes..

The garrison of this fort is composed of six companies (until October 8th last there were seven) of colored troops. Only five white enlisted men are serving here. The officers, of course, are white, and the majority of them have their families here.

The prevailing wind is from the south. The next most frequent wind is the north wind, called here "norther." It is always much colder than its opposite, and is popularly believed to bring more malaria.

The directions of the wind at this Post for the years 1880, 1881, and 1882, taken from the records of the Signal Office here, are as follows. Three observations daily.

1880.		1881.		1882.	
Direction.	No. of Observations.	Direction.	No. of Observations.	Direction.	No. of Observations.
N., . .	247	N., . .	228	N., . .	294
N.E., .	102	N.E., .	58	N.E., .	58
E. . .	43	E., . .	73	E., . .	78

N.W., .	58	N.W., .	96	N.W., .	96
Calms, .	121	Calms, .	95	Calms, .	95

Very soon after beginning to attend sick-call, the preponderance of cases taken upon sick report from certain companies excited the writer's curiosity, and a little reflection led to the belief that the position of the company quarters with reference to the creek had something to do with the facts noted. After being relieved as chief medical officer, the writer spent some days in preparing the following tables, and it seems to him that the fruit of his labor may be of general interest.

TABLE I.

Whole number of cases of malarial disease for nine months, and whole number of days of sickness.

	Cases.	Days.
C Troop, 9th Cavalry, . .	71	231
I Company, 24th Infantry, . .	48	168
C " " " . .	44	139
E " " " . .	39	115
K " " " . .	28	82

D Company, 24th Infantry, left this post for another station October 8, 1883. and G Troop, 9th Cavalry, was "in the field" for nearly four months. To make Table I. more complete, we have:

Table I. A, for seven months.

	Cases.	Days.
C Troop, 9th Cavalry, . .	51	152
I Company, 24th Infantry, . .	35	124
C " " " . .	32	100
D " " " . .	28	91

Table I. B, for five months.

	Cases.	Days.
C Troop, 9th Cavalry, . .	21	57
C Company, 24th Infantry, . .	17	44
E " " " . .	12	34
G Troop, 9th Cavalry, . .	12	29
K Company, 24th Infantry, . .	9	29
I " " " . .	8	22

TABLE II.

Average duration of cases.

	Days.
C Troop, 9th Cavalry, . .	3.25
I Company, 24th Infantry, . .	3.50 (or 3.02)[1]
D " " " . .	3.25
C " " " . .	3.16
E " " " . .	2.94
K " " " . .	2.92
G Troop, 9th Cavalry, . .	2.16

[1] This name arose from an old Indian legend, and not because the water has alleged medicinal qualities.

[1] A case of typho-malarial fever, which terminated fatally after six weeks in the hospital, and which was the only case of continued fever during the period, might, I think, be fairly left out in computing I Co.'s average sickness.

There are, of course, differences in the number of soldiers in each company. Cavalry companies, or troops, as regulations prescribe that they shall be called, number, when full, sixty-six men. Infantry companies number only fifty; however, in actual (mean) strength the companies here during the nine months were nearly equal.[1]

The mean strength of any company is constantly varying from discharges, men being ordered on detached service, etc. With considerable labor, Table III. was prepared. The percentage of sickness to the men of each company actually serving in this Post is here shown.

TABLE III.

Percentum of men sick with malaria in nine months.

C Troop, 9th Cavalry,	.	.	.	135	per cent.
I Company, 24th Infantry,	.	.	.	128	"
C " " "	.	.	.	118	"
E " " "	.	.	.	106	"
K " " "	.	.	.	68	"

Table III. A.

Percentum of men sick with malaria in seven[2] months.

C Troop, 9th Cavalry,	.	.	.	98	per cent.
I Company, 24th Infantry,	.	.	.	94	"
C " " "	.	.	.	89	"
D " " "	.	.	.	71	"

Table III. B.

Percentum for five[2] months.

C Troop, 9th Cavalry,	.	.	.	38	per cent.
G " " "	.	.	.	20	"

Table III. C.

Percentum for one month (Sept. 1883) the most sickly.

C Troop, 9th Cavalry,	.	.	.	46	per cent.
I Company, 24th Infantry,	.	.	.	34	"
E " " "	.	.	.	30	"
C " " "	.	.	.	20	"

Mean strength of the command for the period, 277; total number of malarial cases, 269; per cent., 97. Total number of days lost to the Government by malarial sickness amongst the soldiers, 855. Average duration of all cases, 3.02 days.

A comparison of the tables and the diagram will show that the number of cases of sickness and days of sickness increases in each company as the barracks are nearer the banks of the creek, with the single exception of C Company, 24th Infantry, which holds the third place in Table I., the fourth in Table II., the third in Table III.—Why? Obviously because the quarters of this company lie directly *across* the course of the north wind. Were the south wind as unwholesome as the north, K Company, 24th Infantry, would have the same average of sickness as C Troop, 9th Cavalry, but not so great as C Company, 24th Infantry, because K Company's quarters present a narrow end (twenty-six and a half feet), whereas C Company's quarters offer their whole length to the north and south winds. Leaving out C Company, 24th Infantry, we have a regular gradation, the number of cases, days of sickness, and per cent. of cases gradually diminishing as we go away from the banks of the creek.

Some disciple of Dr. Oldham may say that, as it has been stated above that the north wind is colder than its opposite, may not the chill produced by the sudden changes[1] really cause the malarial troubles? To which the very obvious reply is that there is no difference in temperature between E Company's, 24th Infantry, barracks and those of K Company, same regiment, and yet the one nearer to the creek has the more sickness. I am aware that some remarkable instances have been recorded of the growth of a line of shade trees, or the removal[2] a few hundred yards of a dwelling or barrack stopping malarial fevers, etc. It has even been asserted[3] that screens or mosquito-nets will shut out malaria as well as the insects. But no observations of bodies of men alike in age and condition, eating the same food, wearing similar raiment, performing the same duties, etc., have shown—at least so far as I know, that a difference of residence of less than one hundred feet from the banks of a stream will make a difference in the number of cases of sickness occurring on the *same* days.

There is some diversity in the duties of the cavalry and infantry. The former have horses to groom and water. Therefore G Troop, 9th Cavalry, has been brought into every Table where possible, in order to compare it with C Troop, same regiment.

The banks of the creek afford all the supposed factors for the production of malaria, and to the writer it seems that the course of the malarious sicknesses, during his term as post-surgeon, demonstrates that these factors do produce the specific poison here, which the north wind brings into the post.

That there is as yet an unknown factor, as assumed by Dr. Sternberg[4] and others, seems probable. The malarial virus must, as has often been pointed out, lose its potency very rapidly in the air; otherwise C Company, 24th Infantry, would have the highest, instead of the third place in the Tables, since their exposure is greater to the noxious wind than is that of any other company.

The blacks seem about as liable to malarial poisoning as the whites, in this garrison, but are much more amenable to treatment, as the average duration of cases amongst them (3.02 days) shows.

These soldiers are selected men, mostly young, without physical defects, and, generally speaking, of good habits. Malarial diseases owing to the

[1] It is easier to get recruits for infantry than cavalry regiments among the blacks, and our infantry companies are nearly or quite full. In an Indian country, the cavalry service is generally more arduous.

[2] The computations are made in these tables for those months only in which the companies mentioned in the table were doing duty in the Post together.

[1] Without being able to collect precise data, I dare say that the fall of the thermometer generally exceeds 20° F. within two hours after the setting in of a norther.

[2] See admirable description in Watson's Practice, and other standard text-books.

[3] British Medical Journal, April 1, 1882, Croonian Lecture.

[4] Op. cit.

fever, anorexia, emesis, constipation, loaded tongue, yellowish conjunctivæ, etc., (the first symptom is invariable, and some of the others quite constant) are not easily feigned.

Malingering is mentioned rather to show that as a possible source of error it has not escaped notice, than because it seems probable that it would vitiate the conclusions to be drawn from so large a number of cases.

Could a wall, twenty feet[1] in the sheer, be built along the banks of the creek it would, I believe, improve the health of this command.

MEDICAL PROGRESS.

The Thermo-cautery in the Treatment of Anal Fistule.—Dr. E. Farcy recommends the thermo-cautery in the treatment of fistula in ano, and draws the following conclusions as to its advantages:

1. The operation is rapidly performed, and several fistulous tracts may be operated on at the same time.

2. Chloroform is unnecessary, and there is no danger of either primary or secondary hemorrhage, as by other methods.

3. By this method the vitality of the tissues is excited and there is only moderate suppuration. The wound is protected from the direct influence of the air before granulation sets in.

4. There is no fever, no erysipelas, no phlegmons or purulent infection, no relapse, and the cicatrix is linear. It is therefore the best method for operating in these cases.—*Revue de Thérap.*, April 1, 1884.

Gastrotomy.—A remarkable operation of this kind was performed by Mr. Knowsley Thornton on Tuesday, May 6th, at the Samaritan Hospital. A girl, aged eighteen, who was a patient of Mr. H. P. Symonds, of Oxford, had indulged for some years in the habit—not unknown in the records of clinical medicine—of eating the combings of her hair, and swallowing cotton and other like materials. A large mass gradually collected, which was moulded into the shape of the stomach, and measured nine and a half inches in length, and five in breadth at the cardiac end. The stomach was opened on its anterior surface by an incision five inches long. Very little hemorrhage ensued, and the mass was extracted by means of a vulsellum. During this process, precautions were taken so that neither the wound nor the peritoneum was fouled by the contents of the stomach. The wound was closed by five silk sutures, deep and superficial, interrupted and continuous. A case of a similar kind, which terminated in the recovery of the patient, is recorded by Schönborn in Langenbeck's *Archiv*, vol. xxix., 1883, page 619. Mr. Thornton's patient was doing well at noon on Thursday, May 8th.—*British Med. Journ.*, May 10, 1884.

Resection of Muscles in Infantile Paralysis.—Mr. Keetly has recently undertaken the resection of part of the quadriceps extensor femoris in a case of infantile paralysis, causing inability to extend the right knee. By shortening the weak, relaxed, and partly atrophied muscle, the operator hoped to increase its strength, with the aid of electricity during recovery from the operation. Mr. Willett has already resected the tendo Achillis in paralytic talipes calcaneus, with good results, finding that the shortening of the abnormally elongated tendon enables the muscles of the calf to regain some portion of their lost functions, especially when the muscular wasting has been chiefly due to disease, and has not advanced too far. Mr. Keetly's patient was a boy, aged six, who had suffered from paralysis of the right lower extremity for four years, and the muscular atrophy was not complete, yet sufficient to prevent thorough extension of the knee. A longitudinal incision was made in front of the thigh, about three inches in length, ending an inch above the patella; the skin was held apart by retractors, and one inch of the entire substance of the quadriceps was cut away with scissors, about two inches above the patella. The separated ends were united by means of about one dozen carbolized catgut ligatures. Esmarch's bandage had been applied before operation, and only one small artery required ligature. The wound was dressed with a small iodoform pad and carbolic gauze, and the limb placed on a back-splint at an angle of sixty degrees with the bed. The operation was performed on May 5th. The wound healed rapidly and perfectly, and, when a sufficient time has elapsed, the results will be made known.—*British Med. Journ.*, May 31, 1884.

Porro-Mueller Operation.—Dr. Franzolini performed this operation on May 2, on a woman thirty-six years of age, for pelvic stenosis and deformity from osteomalacia. The fœtus was extracted dead. The pedicle was treated by the extra-peritoneal method, and Listerian precautions were used. All went well until the tenth day, when the patient was seized with a pleuro-pulmonary complication, which carried her off in two days.—*Gazz. Med. di Torino.*, May 15 and 25, 1884.

Laparomyomotomy.—R. Kaltenbach gives a review of his ten cases, with indications for the operation. Of his ten cases eight were supravaginal operations, and two were myomotomies. In these two the tumors were more or less pediculated, and the intraperitoneal method was used. In the eight cases the cavity of the uterus was opened, and the stump treated by the extraperitoneal method. In most of the cases Hegar's operation was employed, that is, with the double elastic ligature around the neck, with the parietal peritoneum sewed up, and the stump rendered aseptic by the actual cautery and chloride of zinc, after being fastened extraperitoneally by lance-needles to the abdominal walls. Only one case, in which the stump was treated by Péan's method, proved fatal. In the case of women who have not come to the menopause Kaltenbach leaves the ovaries.

Large circumference of the tumor, rapid growth with bleeding, severe bleeding, or symptoms of pressure, are the indications for operating. For outward advancement of small tumors toward the abdominal wall Kaltenbach recommends removal by the vagina. The extraperitoneal treatment of the pedicle is to be preferred. The intraperitoneal method should only be used when it insures safety against bleeding and sepsis.—*Centralbl. für Chir.*, May 17, 1884.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, JULY 5, 1884.

BEER-DRINKING AND HEART DISEASE.

THE bodily ills that come of the abuse of drink are so many and so dire that it would appear almost impossible to add to the dreary catalogue of them. Yet BOLLINGER, at a recent meeting of the Ärztlichen Verein, in Munich, called attention to the part played by beer-drinking in the causation of certain forms of heart disease, a subject which, if it be not altogether new to some of our readers, has certainly not been generally understood.

Most writers, it is true, speak very guardedly upon the subject of idiopathic hypertrophy and dilatation of the heart, but Seitz and others have adduced an abundance of evidence to prove that cases in which the fatal termination is directly due to this form of cardiac disease are of frequent occurrence. The records of the Pathological Institute of Munich show that idiopathic hypertrophy of the heart is of much more common occurrence in that city than elsewhere. The observations of several local pathologists confirm this statement. The figures are not without interest. Spatz found among 638 men no less than 55 affected with so-called myocarditis. Among 433 women, there were 23 cases. Among 290 men between the ages of thirty and sixty years were 41 cases of myocarditis, or 14 per cent. Among 144 women at the same period of life, only 10, or 7 per cent., were affected. Hermann's cases showed among 305 sections, 49 examples of plethora-heart as the cause of death in men, while only 3 occurred in women.

Von Buhl regarded these hypertrophies of the heart without discoverable cause, such as valvular lesion or arterial sclerosis, as the result and product of a chronic myocarditis, which usually ended fatally in consequence of fatty degeneration of the muscle. Under the influence of this teaching, and because the patients, as a rule, enter the hospital and die with symptoms of failure of the heart, this form of hypertrophy came to be generally regarded in Munich as the result of an inflammatory process. Bollinger, finding, in most of the cases, no anatomical evidences of inflammation, and just as seldom fatty degeneration, cannot accept this view, and regards the hypertrophy as simple, or idiopathic. At his suggestion, Schmidbauer undertook, by means of exact observations, to establish the extent of this epidemic of cardiac hypertrophy in Munich upon a statistical basis, and to discover its cause. In 1000 post-mortem examinations there were 46 cases, 32 men, 14 women, of undoubted idiopathic hypertrophy of the heart, as the cause of death. As an associated condition—not as the cause of death—idiopathic hypertrophy of the heart was found in 33 other cases, 23 men, 10 women. All cases of enlargement of the heart due to lesions of the valves, or disturbances in the pulmonary circulation, or associated with arterial sclerosis, or granular atrophy of the kidneys, were of course excluded. Certain of these cases of idiopathic hypertrophy of the heart were, perhaps, to be accounted for by prolonged excessive muscular effort and bodily strain. But the greater number, as was determined by carefully worked-out personal investigation, particularly among suicides, were explicable only by habitual excesses in beer-drinking in connection with a true plethora, the existence of which has, however, been of late denied by a majority of physiologists and pathologists.

The habitual consumption of beer in excessive quantities tends to hypertrophy by the direct action of alcohol upon the heart, by the enormous amount of fluid introduced into the body, and by the easily assimilated nutritive constituents of the beer itself. Furthermore, such habits are often associated with great bodily activity and an at least relatively luxurious manner of life. The average weight of the normal heart in men is relatively greater in Munich than elsewhere, a fact, without doubt, dependent upon the excessive consumption of beer in that city. The characteristic changes in the form of hypertrophy under consideration consist in the participation of both sides of the heart, and in an enormous increase in the volume of the primitive muscular elements, with enlargement of the nuclei. Whether or not actual numerical increase in the muscular fibres takes place cannot be known.

Many individuals addicted to such excesses attain an advanced age notwithstanding cardiac hypertrophy, by reason of constitutional peculiarities, an active open-air life, or an enforced moderation, but the

greater number perish after brief illness with symptoms of cardiac failure. At the post-mortem examination are discovered moderate dropsy, pulmonary œdema, brown induration of the lungs, bronchitis, congestion of the lungs, liver, spleen, kidneys, and other organs. Fatty degeneration of the muscular wall of the heart is absent in most of these cases, and death must, in the absence of adequate anatomical lesions, be looked upon as due to paralysis of the cardiac nerves and ganglia.

The condition of such subjects not rarely amounts to a true plethora of the most typical kind, such as is seen among the drivers of beer-wagons and workers in breweries in this country.

The frequency of idiopathic hypertrophy of the heart in men, in whom it is apt to prove fatal in the very prime of life, is in strong contrast with its infrequency among women. The latter also suffer from less pronounced forms of the affection.

It is interesting to note that while the average amount of beer consumed during the year 1882 elsewhere in Germany ranged, in different districts, from 54 to 186 litres for each person, in Bavaria it reached 233 litres, and in Munich 432.

These facts constitute an important contribution to the subject of the non-valvular affections of the heart, and are, from their obvious bearings and the favorable circumstances under which they have been studied, of great value in their relations to practical hygiene. The excesses in beer common in some parts of Germany are rare in the New World, but that such excesses are attended by a direct and grave danger, hitherto little suspected, should be generally understood. It is unfortunately a sermon little likely to reach or to be heeded by those to whom its lessons would be of greatest use.

THE PROPHYLAXIS OF TUBERCULOSIS.

THE prophylaxis of tuberculosis was recently considered at a meeting of the Hygienic Section of the Vienna College of Physicians, and a committee, consisting of HEIN, SCHRÖTTER, WEICHSELBAUM, KAMERER, KOWALSKI, and KRATSCHMER, reported a series of directions based on a recognition of Koch's views, which are published in the *Wiener medicinische Wochenschrift* of May 10th.

In the first place, it is assumed by the committee as demonstrated, that the expectoration of individuals with cavernous excavations of the lungs, and the fecal discharges of those having intestinal tuberculosis, are the chief sources of transmission of the disease; hence, it is to such cases that precautions apply. In apartments occupied by such, an abundance of fresh air should be provided, the floors and walls, body- and bed-clothing should be kept scrupulously clean; because it is the dried sputum and the infectious excretions adhering to them which gradually become pulverulent and so liberate the ever-living and dangerous bacilli. To the same end, expectoration into handkerchiefs should be discouraged, and spit-cups should be substituted. The drying and pulverization of non-disinfected expectoration outside of the sick-room should be prevented by the frequent emptying of spittoons, and disinfecting the contents with a five per cent. solution of carbolic acid. Especially should this be done where many persons are grouped together, as in hospitals, lecture-rooms, asylums, barracks, railway stations, and, above all, where large numbers of phthisical persons are grouped together, as at health resorts especially frequented by phthisical cases. So, too, disinfection should extend not alone to expectoration and to alvine dejecta, but to other discharges from tuberculous tissues and organs, as the pus from tuberculosis of the skin and of bones, as well as to bandages, and bed- and body-clothing which become soiled with the discharge.

The disinfection of clothing which can be washed is to be accomplished by boiling for an hour with sodium carbonate, while other materials are purified by exposure for an hour to dry heat at a temperature of 212° F., or to the action of steam at the same temperature, and for the same length of time.

Persons with advanced tuberculosis should, as far as possible, be isolated from other members of the family, and where this is impossible, hospital treatment should be provided; especially should infants and feeble children be removed from households which include such cases. Close proximity of places of sleeping, and especially the sharing of the same bed by healthy persons and those affected with phthisis should be avoided, while especial care should be taken to secure the necessary isolation of cases of advanced phthisis where the residence happens to be a store for the sale of articles of food. Marriages of persons with tuberculosis should be forbidden, with a view to preventing at once the transmission of phthisis from man to wife, and to posterity.

Since the effect of the various affections of the respiratory organs is to increase the predisposition to tuberculosis, the possibility of the occurrence of such diseases should be reduced to a minimum. Hence everything should be done to diminish dust formation within doors and in the streets. Measures to this end are proper house-cleansing and street-cleansing regulations. And for the same reason, physicians should coöperate with the civic authorities in preventing the spread of whooping-cough and measles.

The use of the milk of cows affected with bovine phthisis should be discouraged, while that from animals having tuberculosis of the udder should be positively prohibited. Such milk should only be

taken after having been well boiled. The use of the flesh of animals similarly affected should be forbidden.

The rules of prophylaxis include some which are not justified either by the dictates of humanity, or by clinical experience; as, for instance, the isolation of the sick from their friends and families, and remanding them to hospitals where they not only miss the sympathy which is so comfortable to the sick, but may even suffer for want of proper nursing.

There can be no doubt, however, that advantage will result from the systematic consideration of these suggestions. Hitherto partially observed measures will thus be more rigidly carried out, and new measures enforced, while it is scarcely likely that at the present day hardships will be practised on the unfortunate whose lot is already sufficiently sad, without the additional pang of separation from friends.

In the discussion which followed the reading of the report there was much difference of opinion, the question being chiefly as to whether a stringent observance of the regulations suggested should be insisted upon, or whether some latitude should be allowed, the prevailing view rather favoring the latter, toward which we must express our own inclination.

THE MODE OF ORIGIN OF GENERAL MILIARY TUBERCULOSIS.

ALTHOUGH it has been for some time recognized that a very large number of cases of general miliary tuberculosis are secondary to primary foci, it cannot be said that we have had, until quite recently at least, any accurate information as to the *modus operandi* of such foci.

BUHL early asserted that the general process originated in absorption from a softening mass of cheesy matter, but how this took place, and why in the majority of instances the cheesy focus fails to give origin to secondary miliary tuberculosis, he did not explain. PONFICK'S discovery of tuberculosis of the thoracic duct, and WEIGERT'S of tuberculosis of the veins, brought us a step nearer to the solution of the problem. The latter published, in 1879, three cases of acute general miliary tuberculosis in which he had discovered a large thrombus-shaped tubercular focus in a pulmonary vein, which he regarded as the starting-point of the tuberculosis. In 1882, he reported nine cases of acute general miliary tuberculosis, in seven of which he found tuberculosis of veins, and in two tuberculosis of the thoracic duct. The former appeared as true tubercular infiltrations of the vessel walls, projecting into the interior of the vessel in a thrombus-like, or polypoid manner, smooth, except at a single point of ulceration, and centrally cheesy. Upon these observations Weigert based the assertion that *acute general miliary tuberculosis*, in adults at least, *depends upon a tubercular focus either in a vein or the thoracic duct*—ascribing the acute tuberculosis to the sudden introduction of a large quantity of tubercular poison, either from a large focus, or numerous small foci, while that form of general miliary tuberculosis in which only a few nodules are found in separate organs, is ascribed to the disintegration of a small vein-tubercle. So, too, the nodules of varying size and limited number found in the spleen, liver, or other organs, along with pulmonary tuberculosis, he ascribed to the introduction of a small amount of tubercular matter into the blood.

Quite recently, WEICHSELBAUM, in the *Wiener med. Wochenschrift*, No. 12, March 22, has apparently supplied the missing link in the proof of this proposition, by the publication of three cases of acute general miliary tuberculosis in which, associated with tuberculosis of the veins, he found tubercle bacilli in the blood of the patients, after death. The first case was that of a young woman of twenty-five, who died of phthisis six days after aborting of a four months fœtus. She had suffered with cough, shortness of breath, and fever for some weeks previous. The autopsy revealed tuberculosis of the uterine veins at the insertion of the placenta, both Fallopian tubes distended with cheesy matter, and their mucous membrane injected, thickened, and infiltrated with small nodules. Some of the cheesy and softened tubercular nodules as large as a pea, and containing nests of closely packed bacilli, protruded into the lumen of the veins and fused with the thrombi found in their interior. Out of twelve slides of blood from a heart-clot—clotted blood was used because of its containing a large proportion of bacilli—four contained the parasite.

The second case was a man of forty-three, in whom a branch of the pulmonary artery in the right upper lobe contained a polypoid tubercle larger than a bean, ulcerated at one point, cheesy at its centre, and continuous with a large cheesy focus in the same lobe. Preparations from a white thrombus from the left ventricle contained relatively numerous bacilli in groups of from two to six, as did also fresh coagula, and even fluid blood from the femoral vein, although in smaller numbers.

The third case exhibited, besides general miliary tuberculosis, cheesy foci and bronchiectasis, a cheesy abscess about the tendon of the right supinator longus muscle, and chronic tuberculosis of the seminal vesicles, the left vas deferens, the epididymis and prostate. A cheesy mass surrounded a large vein of the pudendo-vesical plexus, and in one place had perforated the vein. Out of nine preparations made from heart coagula, two contained bacilli.

Weichselbaum believes it a necessary inference from these facts, that in chronic general miliary tuberculosis, that is, the form in which along with pulmonary tuberculosis single nodules of different

size and age are found in the liver, spleen, or kidneys, these secondary deposits arise in the same way, even though the bacilli are not found in the blood, since they may easily escape detection when few in number. In support of this view, Weigert has found in two cases of this kind small tubercles in the walls of veins.

REVIEWS.

M. PASTEUR—THE HISTORY OF A SAVANT.

THIS is the title of a little volume, the fourth edition of which has been recently issued in Paris. Louis Pasteur was born December 27, 1822, and is, therefore, in his sixty-second year. He showed, when a young man, great ability as a painter, but gave himself especially to the study of chemistry, making in this department of science important discoveries. His first public position seems to have been that of assistant professor of chemistry at Strasbourg, and, while living in that city, a curious story is told of him. He was engaged to be married, but, when the wedding-day came, seemed to have forgotten, in his scientific pursuits, the appointed event, and had to be sought in his laboratory, and reminded that the time had come for his marriage. When thirty-two years of age, he was appointed Dean of the Faculty of Sciences at Lisle. As one of the chief industries in the department in which he lived was the manufacture of alcohol, he determined to give part of his lectures to the study of fermentation, and thus began those wonderful investigations by which he has opened a new world to science. Although not a physician, he has probably done more to influence medical theories and therapeutics than any man of the century.

When his doctrine of an attenuated virus of certain malignant diseases of inferior animals was announced in the Academy of Sciences, Bouley exclaimed: "A new doctrine is revealed for medicine, and this doctrine seems to me powerful and luminous. A great future is at hand; I anticipate it with the faith of a believer, and the zeal of an enthusiast."

We cannot follow his biographer in his sketch of Pasteur's subsequent studies of spontaneous generation —a doctrine which, we need not tell our readers, he utterly rejects—of wine, of the diseases of the silkworm, of beer, of chicken cholera, of malignant pustule, and of septicæmia.

In 1868 overwork brought hemiplegia, and even then, when he was expecting death, he dictated to his wife a note upon the studies so dear to his heart, and which was communicated to the Academy of Sciences. He has never completely recovered, and the members of the left side are still impaired in motion.

The French government has liberally provided for his researches. The ancient garden of the old college Rollin has been placed at his disposal, and there he has built stables for horses sick with glanders; stables, too, for diseased sheep, and a kennel for dogs with hydrophobia. On the ground floor of the laboratory, he has collected a world of animals for experiments—dogs, hens and chickens, rabbits, and guinea-pigs. In all vivisections, the animal is chloroformed, and Pasteur remarks—the words are well worthy the attention of antivivisectionists—"Never have I had the courage to kill a bird in hunting; but when experiments are concerned, no scruple stops me. Science has the right to invoke the supremacy of the end."

His biographer gives a graphic account of a visit made by Pasteur and himself at the call of a *veterinaire*. It is mentioned that there does not occur at Paris a case of hydrophobia to which Pasteur is not called. They went taking with them some rabbits, for the purpose of having them bitten by the dog. They found a huge bulldog, howling and frothing in his cage, and an effort was made by putting an ear of one of the rabbits between the bars of the cage to have it bitten, but failed, and Pasteur said, "Nevertheless it is necessary to inoculate these rabbits with the saliva." The dog was then lassoed, drawn out of the cage, the jaws tied, and, stifled with rage, eyes injected, the body shaken with a violent spasm, fixed upon a table, when Pasteur, bringing his own head a finger's breadth from the dog's covered with froth, aspired with a tapering glass tube some drops of the saliva. The biographer remarks that it was in this terrible *tête-à-tête* Pasteur has appeared to him the grandest.

SOCIETY PROCEEDINGS.

MEDICAL ASSOCIATION OF THE COUNTY OF NEW YORK.

Stated Meeting, June 16, 1884.

THE PRESIDENT, WM. DETMOLD, M.D., IN THE CHAIR.

DR. J. LEWIS SMITH read a paper on

THE SUMMER DIARRHŒA OF CHILDREN.

This, as was well known, he said, was principally confined to children under two and a half years of age, and was much more common and fatal in cities than in the rural districts. Of late years, it was gratifying to know, however, that the mortality from this cause had been somewhat controlled in consequence of the exertions of health boards and of the effect of other agencies. Still, it remained the great scourge of the community during the summer months. In the year 1882, the deaths in New York from diarrhœal diseases in children under five years of age for the different months were as follows:

January,	34 deaths.
February,	50 "
March,	57 "
April,	63 "
May,	72 "
June,	231 "
July,	1053 "
August,	877 "
September,	382 "
October,	195 "
November,	68 "
December,	35 "

Among patients over five years of age suffering from diarrhœal diseases, the deaths for the different months of the same year were as follows:

January,	14 deaths.
February,	15 "
March,	14 "
April,	20 "
May,	15 "
June,	19 "
July,	131 "
August,	149 "
September,	84 "
October,	55 "
November,	31 "
December,	24 "

It would thus be seen that in the year 1882 there were nine times as many deaths during the five months from the first of June to the last of October as during the remaining seven months of the year; while in the same year seven and a half times as many persons under five years as over that age died from diarrhœa. These figures probably represented very fairly the average ratios in large cities. In the last three years in which the New York Board of Health issued annual instead of weekly reports, the deaths from diarrhœa for the various months were as follows:

	1873.	1874.	1875.
January,	94	43	46
February,	84	34	52
March,	97	80	58
April,	114	47	45
May,	95	61	89
June,	220	147	157
July,	1514	1005	1387
August,	967	1007	1012
September,	424	587	608
October,	213	255	185
November,	87	105	57
December,	53	56	50

In these three years there were altogether 9855 deaths from diarrhœa, and all but 1407 of them occurred in children under five years. The same general facts were true in regard to other cities in the United States and Europe; although in many of them the proportionate mortality was not so great. In country towns and villages, and in the rural districts generally, on the other hand, cases of diarrhœal disease occurred comparatively rarely, and were usually of a mild type.

There were two distinct factors in the causation: *first*, the atmospheric; and, *second*, the dietetic. In regard to the first, the prevalence of diarrhœa corresponded closely with the increase of atmospheric heat. In New York, it commenced in May and reached its maximum in July and August, when it constituted by far the most frequent and dangerous disease met with in the city. In September it began to diminish again. In October, however, the mortality from it was always considerably greater than during the month of May, although the average temperature was lower than in the latter; which would seem at first to be contrary to what we would naturally expect. But this was explained by the fact that the deaths were usually those of infants who had contracted the disease during the summer, and had never recovered from its debilitating effects.

The fact was, therefore, an undisputed one, that the summer season was one of the great causes of the diarrhœa. The exact causative agents in its production were not, however, so easy to arrive at; since much the same degree of heat prevailed in the rural districts as in the cities. It seemed probable, therefore, that noxious effluvia constituted or contained the morbific agent. One year, on the 10th of May, in an institution with which Dr. Smith was connected, an offensive odor was noticeable in the building, which was found to come from a manure heap on some neighboring premises; and in consequence of the emanations from it four children (of whom one died) were taken with diarrhœa. He also mentioned the fact that once, when visiting a tenement district in the city on behalf of a citizens' association, he found that in the part of a certain street lying between two avenues, which was compactly built up on both sides with wooden tenement-houses, nearly every infant was ill with diarrhœa.

The population was almost exclusively foreign, and there being no sewers, all the refuse of the houses was thrown into the street. Water was also constantly poured out into it, and the decay of the vegetable and animal substances in the hot summer weather rendered the whole air foul and stifling. In another locality, where there were a number of tripe-dealers and a low class of butchers, who were accustomed to resort to bone-boiling, diarrhœa was very prevalent and fatal both in the street and the adjoining neighborhood. Murchison found that twenty out of twenty-five boys were attacked with diarrhœa, which was excited by the effluvia from an old drain near the school which they attended, and the purgative effect of impure air was everywhere well recognized. Thus, medical students previously in good health were not infrequently attacked with diarrhœa as the result of working in the dissecting-room.

Whether organic impurities giving rise to diarrhœa were organized or not, was not yet definitely determined. A bacillus of cholera infantum, it was true, had been discovered; but whether it was a causative agent, or merely an incidental concomitant, was still an open question. Dr. Smith then referred to certain gases and gaseous combinations liable to be found in the air which were supposed to have a purgative effect; and among the most active chemical compounds in this respect were the sulphates. In all large cities solid impurities were very numerous in the atmosphere, as could be readily seen by observing the air lit up by a pencil of sunlight; and this accounted, in great part, for the hazy cloud that could usually be seen hanging over towns and cities. In the present state of our knowledge, we had to be content with saying that impure air was one of the great causes of infantile diarrhœa, without being able to state precisely its *modus operandi*. This led us to the presumption, however, that, in addition to heat, there were infectious germs; and the conditions existing in the summer in cities were certainly favorable to the development of low organisms. In this connection, Dr. Smith referred to the various evils incident to the life in crowded tenement-houses as specially liable to result in the production of diarrhœa among infants and young children.

He then passed on to the consideration of the second great cause—the dietetic. The mode of feeding was a most important element in the causation of diarrhœa,

and, in cities, infants under eight months old, if bottle-fed, almost invariably contracted the disease in summer. In institutions it was a well-known fact that every bottle-fed child under four, and even six months died at this season. Among the tenement-house population, one great trouble was that young children were given fruit and ordinary table-food; and hence the second summer, when the infants were no longer nursed at the breast, was always regarded with peculiar apprehension. Occasionally it happened that from continued ill-health the milk of the mother or nurse became deteriorated (containing cholesterine), and would not agree with the infant. A quiet life, devoid of any active excitement, was essential to the proper performance of lactation; as was especially shown in the cases reported in the *Louisville Medical Journal*, in which venereal excesses on the part of wet-nurses were followed by the sudden death from diarrhœa of the infants to whom they were giving nourishment. All authorities agreed that nothing was so good for infants as breast-milk; but where they were deprived of this, cows' milk was, as a rule, the best substitute for it. The trouble with the latter, however, was, that if it came from cows fed in or near the city, it was apt to be deficient in nutritive qualities; while if it was brought from a distance, lactic acid formation was liable to commence before it could be used. Hence it was that such a variety of prepared foods had been suggested.

In New York, improper feeding was quite sufficient to produce diarrhœa without the influence of atmospheric conditions; but where the two causes were combined, it was not to be wondered at that the infant mortality was so large during the summer months. Before the establishment of the present Foundling Asylum, all foundlings were sent to the Almshouse on Blackwell's Island, where they were entrusted to the care of pauper women, who were filthy and careless in their habits, and who fed them with improper diet. The consequence was, that such children, as a rule, always died of diarrhœa before reaching the age of two months, and if by any chance one of them occasionally lived for a longer period than this, it was regarded with profound wonder. Here, again, the two great factors in the causation of the trouble were foul air and improper food. Since the Foundling Asylum had been organized, he was happy to say, many of these little waifs were rescued from death.

At this point he alluded to the supposed influence of dentition in the etiology, and stated his positive conviction that this was not in reality a cause. This, he thought, was proved by the fact that infants under three or four months (not having as yet reached the age of dentition) were quite as liable—and even more so—to diarrhœa than the older ones in whom the process was taking place.

On account of the length of the paper, Dr. Smith was obliged to omit considerable portions of it in the reading, and he therefore passed over the description of the symptoms, merely pausing to remark that in the great majority of cases the disease began very gradually. Hence mothers were very apt to let the trouble run on for one or two weeks (under the impression that it was due to dentition and was really beneficial to the child) before calling in the services of a physician. Vomiting, as a rule, was not an early symptom. But there were certain sudden and severe cases which were properly designated as cholera infantum. This term, he thought, should be restricted to those cases in which the symptoms were much more violent than ordinary. It was almost as severe as true Asiatic cholera, and in no other disease except this was such a marked change in the appearance of the patient so quickly produced. It was also sometimes called cholera from diarrhœa; and it was fortunately not so frequently met with now as formerly.

In referring to the anatomical characters of the disease, he stated that he was firmly convinced that it was an inflammatory affection from its very commencement. In eighty-two cases, of which he had the records, he had made careful post-mortem examinations, and had found in all of them marked hyperæmia, which was confined for the most part (although not exclusively) to the ilium and colon. Hence it was, in reality, an ilio-colitis.

Omitting the consideration of the diagnosis and prognosis, and of the best preventive measures, he passed on to speak of the curative treatment, which, he said, comprised four essential points, viz.:

(1) To give the best available food.

(2) To supply the child with pure air.

(3) To aid digestion.

(4) To use such medicinal agents as could be safely employed to check the diarrhœa.

If the mother was not able to nurse her child, and a wet-nurse could not be provided, it became the physician's duty to recommend some substitute for breast-milk. At a very important conference of German physicians of eminence in connection with diseases of children, held at Salzburg, in 1881, all the delegates agreed that human milk contained all the requisite physiological elements quantitatively and qualitatively suited to the growth and development of the infant, and that where this was not available, animal milk constituted the best substitute. Of the many prepared foods now in the market, it was declared that they could in no way substitute mother's milk, and their use was strongly condemned. It was unfortunately the fact, however, that cow's milk in cities was extremely apt to be defective, and likely to be itself one of the causes of diarrhœa. An analysis of the various infants' foods showed that all which consisted to any extent of cow's milk differed widely in constitution from mother's milk. Nestle's food, however, where it seemed to agree with a child, was probably beneficial from the large amount of Swiss condensed milk which it contained. How to modify cow's milk so as to make it resemble human milk as closely as possible, was one of the most important suggestions that emanated from the German conference referred to; and this modification was made by peptonizing the milk. This peptonizing had the effect of rendering the casein, which was the chief source of indigestion, easily digestible, and the process was to be suspended as soon as the milk began to assume a bitter taste. In peptonized cow's milk the casein was found to be in delicate flakes instead of the hard masses in which it ordinarily existed in this fluid. For this very important advance in infant dietetics the profession was indebted to Pfeiffer, of Wiesbaden. In order to have the milk in the best possible condition for the child's use, it was necessary to peptonize it in small quantities as required. Dr. Smith then described the way in which

the infant's diet now used at the New York Infant Asylum was prepared; five grains of Fairchild's extractum pancreatis and ten grains of sodium bicarbonate are added to one gill of warm water and one pint of cow's milk. The liquid should be tasted frequently during the course of preparation, and as soon as it became in the slightest degree bitter, the peptonizing should be arrested. This could be done either by applying heat or placing the milk on ice, and the latter he considered preferable, as it only suspended the process (which it was desirable should be renewed in the child's stomach); while the application of sufficient heat to arrest it had the effect of destroying the ferment. Of this peptonized cow's milk, one part to three parts of water should be used for a child of one month or under, one part to two parts of water for a child of three months, and a dilution of from one-third to one-quarter water for a child of six months. Before the process of peptonizing was resorted to, barley-water was frequently used to dilute the milk, under the supposition that the farinaceous substances mechanically separated the cakes of casein into smaller masses, and this was probably the next best substitute. Baron Liebig had been the pioneer in directing a physiological substitute for mother's milk, and by his process of converting starch into grape sugar had conferred a great favor on humanity. Having spoken of the use of wheat flour and malt extract in the preparation of diet for infants, he alluded to several of the foods now used to a considerable extent in this country. To such as Ridge's food and the imperial granum, milk had to be added, as they contained none. In speaking of condensed milk, he said that Borden's milk, as served fresh from the wagon, contained no cane sugar; while this was always a constituent of the canned condensed milk. To select the best food for an infant was one of the most important duties of the family physician. The portion of the paper devoted to the medicinal treatment of summer diarrhœa was omitted.

DR. H. A. POOLER, of Goshen, New York, said that, having some years ago been obliged, on account of ill-health, to give up his practice in New York and remove to a farm, he had taken great interest in the investigation of the milk-supply of the city, and had endeavored, so far as he was able, to assist in the correction of some of the evils attendant upon it. Mother's milk was the natural food of the infant, and it was supplied to the child at a temperature of from 98° to 100°. In comparing mother's milk with good commercial cow's milk, it was found that they each contained about three and a half per cent. of fat. The great difference between them was in the quantity of casein; the mother's milk containing only about two and a half per cent. of it, and cow's milk about six per cent. In addition, the casein of cow's milk was harder and more difficult of digestion. If cow's milk were diluted one-half with water, the quantity of casein, it was true, was reduced one-half; but, unfortunately, the fat was also reduced in a like proportion. The child fed upon such diet, therefore, was deprived of one-half its natural source of growth, and enfeebled digestion and an unnourished body would be the result. But the child was also robbed of its nourishment to a greater extent than this. The milk before it was dispensed in the city passed through the hands of a number of dealers and speculators, by whom from forty to sixty per cent. of water was added to it. Even this, however, was not all. The milk, instead of being produced within a radius of sixty miles of New York, as it should be, was, as a rule, brought from very long distances. This was because it could be purchased at lower rates at a distance, and the competition was so great that the farmers near the city did not receive sufficient compensation to pay them for providing a regular supply of unadulterated milk. In consequence, the milk was from forty-eight to fifty-four hours old by the time it reached the consumer's residence. The dealers were not scrupulous, however, and if the milk became turned before it was delivered, they did not hesitate to add to it borax, soda, or other substance which might prove injurious to an infant's stomach. In this diluted milk, brought from such a long distance, there was very apt to be found a large amount of peculiarly hardened casein, resulting from the removal of fat, which was known among milkmen as "hickory curd." Finally, in order to keep the milk for the long time that was required, it was necessary to add a large lump of ice to each can, and this ice, being usually gathered from low and shallow ponds, was often filled with organisms that were exceedingly liable to be a source of irritation and disease. In addition to the hard curd, the presence of foreign substances, both animal and vegetable, in the milk was unquestionably a not infrequent cause of diarrhœa in children.

It was the duty of the medical profession, who were the custodians of the public health, to see that there should be a reform in this matter; and a good deal had already been accomplished towards it. Of late, the reprehensible practice of giving cows fermented food had been less common than formerly; and a bill had recently been passed by the legislature which prohibited this entirely. The New York City Board of Health and the State Boards of both New York and New Jersey had been appealed to to provide that the milk supply should be as good and as free from adulteration as possible, and, in consequence of this action, the quantity of milk brought to New York had been reduced by one hundred thousand quarts. The result of this improvement in the quality of the milk was, that while in 1882 there were 19,000 deaths from diarrhœa, in 1883 this mortality was reduced by 3664; and it was hoped that in the present year there would be a still greater reduction. There was plenty of good milk to be had within a comparatively short distance of New York, if the farmers could only be sufficiently encouraged to produce it, and he trusted that every one of these present would do what he could in improving the milk-supply of the city. If each one would select some milkman in his district, and, having convinced himself that the milk which he sold was of good quality, would recommend him to his patients, no little good would be accomplished in the establishment of a high standard for milk, which it would be to the interest of the dealers to maintain. In conclusion, Dr. Pooler recommended that when milk was diluted with water for young infants, a sufficient amount of good cream should be added to make up for the reduction of fat that was caused thereby, and also laid special stress upon the importance of giving the milk to the child at a temperature of 98° to 100°, instead of 40° to 60°, as was so commonly done.

PROF. LEEDS, of the Stevens Institute, at Hoboken, who, like Dr. Pooler, had been especially invited to

take part in the discussion, said that Dr. Smith, in his paper, having called attention to the intimate relations existing between the thermal curve and summer diarrhœa, and having pointed out that heat alone was not sufficient to produce the disease, he wished to speak for a moment of the complicated atmospheric conditions of crowded cities, and to call attention to one point that seemed to have been greatly overlooked. When a short time since he had been called upon by the engineers engaged in selecting a new water supply for the city of Philadelphia to recommend one that would answer the purpose desired, and was making analyses of all the available sources of supply in Eastern Pennsylvania, he was greatly embarrassed to know what standard of purity he should take with which to compare the various waters. It occurred to him that perhaps rain-water, which came direct from the clouds, would be the best standard of comparison; but he was disappointed in not being able to find any statistics whatever in regard to the variations to which rain-water might be subject under different circumstances and conditions. He therefore made himself an analysis of various specimens of water from rain, fog, and snow, and found to his surprise that all the rain-water which he examined was far more impure than the water taken from the head-waters of the Delaware, Lehigh, Schuylkill, and other streams investigated. This was due, without doubt, to the fact that the rain washed a vast amount of impurities out of the atmosphere as it fell. Dr. Smith had alluded to gaseous and organic matters (the latter probably containing germs), as causes of diarrhœal disease, and he had found a large amount of disagreeable organic matter in rain-water. It seemed to him astonishing that the medical profession had not provided itself with information as regards the purity or impurity of the atmosphere, or medical climatology, as it might be called, and he thought it would be an excellent thing if the Signal Service Bureau of the United States could supplement its meteorological reports with reports of the proportion of oxygen, organic matters, etc., in the atmosphere.

As regards the matter of infant feeding, he was of opinion that we were nearer a practical solution of this important problem than had been deemed possible ten years ago. This had been indicated by Dr. Smith, who had rightly attributed great importance to the results of the conference of German physicians to which he had referred. All authorities were agreed that cow's milk was, on the whole, the best substitute for mother's milk, and the practical point, therefore, was to determine what was the best way of preparing it for the infant. We did not know at the present time precisely what the elements were which made up the so-called casein of cow's milk; it having been ascertained simply that they were coagulable by acids. We did know, however, that there was a difference in the percentage and in the character of the albuminoids and the fats in cow's milk and in human milk, while the milk-sugar was precisely the same in both. As Dr. Smith had mentioned, Pfeiffer had demonstrated that the casein of cow's milk could be rendered similar to that of human milk by peptonizing it. As to the fat in human milk, it was not all appropriated, since twelve per cent. of it, as a rule could be found undigested in the feces of the infant. It was, therefore, supplied in excess by nature. In cow's milk the average quantity of albuminoids was twice that found in human milk. In the preparation of a substitute for the latter, he would suggest that to a pint of good cow's milk one pint of water should be added. If to this mixture two ounces of cream and four hundred grains of milk-sugar were added, the percentage constitution of the fluid would resemble very closely that of mother's milk. If, furthermore, the insoluble casein of the cow's milk were converted into soluble peptones by the action of extractum pancreatis, as recommended by Dr. Smith, it seemed to him that we should have a reliable substitute for the natural food of the infant which would probably give satisfactory results if practically tested. The recent advances made in regard to this subject would, in the near future, he thought, work untold good in the reduction of the now enormous mortality among infants and young children.

DR. WILLIAM H. WELCH then presented specimens of

PRIMARY TUBERCULOSIS OF THE GENITO-URINARY APPARATUS.

The patient from whom they were taken had been in Dr. Gouley's wards at Bellevue Hospital. He was an Italian, twenty-five years of age, and was admitted, in April last, suffering from a purulent discharge from the urethra, swelled testicle, with enlarged epididymis, and elevated temperature. The history was a very obscure and meagre one. Under treatment, the discharge became greatly diminished, and the swelling of the testicle subsided; but the temperature continued high, and the general condition grew worse instead of better —the patient being affected with great weakness and frequent sweats. The diagnosis of acute interstitial nephritis (surgical kidney) was made, and he died June 3d. At the autopsy, primary tuberculosis affecting a large portion of the genito-urinary tract was found. It seemed to begin in the left epididymis, which was enlarged, mostly in the globus major, the distended tubules being filled with cheesy matter. The testicle itself was involved, but, undoubtedly, secondarily. The trouble in the testicles was confined to the left one; and the corresponding vas deferens was also affected. The caseous substance mentioned could be traced up to the situation of the seminal vesicles and prostate gland. In that position, behind the neck of the bladder, a cavity of the size of an orange (a tuberculous abscess) was found, and this had completely destroyed the seminal vesicles, as well as all the central portion of the prostate gland. At one point it opened into the prostatic portion of the urethra; and this opening had undoubtedly existed during life. The lateral lobes of the prostate gland were comparatively unaffected. Miliary tubercles were found throughout the whole length of the urethra, as well as in the bladder. The left ureter was dilated and filled with the same cheesy matter as other portions of the genito-urinary apparatus, and the kidney on that side was also immensely enlarged. It was the seat of extensive tubercular disease, the structure of the organ having been destroyed to a considerable extent, and the parenchyma being filled with cavities containing cheesy matter. The right kidney was free from tubercles, but was enlarged, and, together with the left one, was affected with interstitial nephritis. The glands back of the rectum were filled with

cheesy matter; but no other glands in the body were affected.

The interesting points in regard to this case, Dr. Welch said, were: 1. It was a pure and unmistakable case of primary tuberculosis of the genito-urinary apparatus. 2. There was a mixed infection—the gonorrhœal with the tuberculous. It was not absolutely certain that the patient had had gonorrhœa, but this was highly probable, as the swelling of the testicle was of the kind characteristic of gonorrhœa, and not such as was ordinarily met with in tuberculosis of the organ. In addition, the so-called micrococcus of gonorrhœa had been found to be present. 3. The tubercular disease was confined to the left-side organs. This was certainly merely an accident as regards the kidney, as, since the tubercles were scattered over a considerable portion of the interior surface of the bladder, there was apparently no more reason why the left ureter should have become affected than the right.

In connection with the above specimens, Dr. Welch exhibited several other kidneys which were the seat of primary tuberculosis. One of them was very large, and completely filled with cavities containing cheesy matter. It was taken from a man who was the subject of Pott's disease, and who had also been suffering from psoas abscess, and in connection with the latter there was a tuberculous sinus through the ureter. There was also tuberculosis of the peritoneum, and primarily it had been a case of tuberculous caries. There was a great difference when tubercle gained access by means of the blood-current and when it was transmitted from mucous membrane. In the latter case the destruction of tissue was much more marked, and large cavities were formed, very much as in the lungs. In the specimens of tuberculous kidney exhibited, the mode of infection had been by way of the ureter.

In conclusion, Dr. Welch referred to the existence of the bacillus tuberculosis in the urine of those suffering from tubercles of the kidney, which had first been discovered a little over a year ago. It could by no means always be found, even when searched for with the utmost care, but, if it were found, it constituted a point of the utmost value in diagnosis. In one case he had been successful in finding it, and the diagnosis was afterwards confirmed by autopsy. At post-mortem examinations the bacillus was seldom observed in the caseous matter filling cavities, but he had found it common around the borders of the cavities.

INDIANA STATE MEDICAL SOCIETY.

Annual Meeting, held in Indianapolis, June 10, 11, and 12, 1884.

TUESDAY, JUNE 10TH—FIRST DAY.

THE Society was called to order by THE PRESIDENT, S. E. MUNFORD, M.D., of Princeton, at 10 A.M., in the Plymouth Congregational Church.

DR. E. S. ELDER submitted the *Secretary's Report*, showing a reported membership of 1006.

DR. GEORGE H. KEMPER then presented the *Treasurer's Report*, showing a total balance of $265.41.

PUBLICATION OF THE PROCEEDINGS.

A proposition was received from Dr. F. C. Ferguson, editor of the *Indiana Medical Journal*, offering to publish the proceedings of the Society in the journal under the supervision of the publishing committee and to furnish each member of the Society a copy for one year, provided the Society will pay him the funds that have heretofore been devoted to their publication in book form.

The proposition was referred to a Special Committee, consisting of Drs. Hibberd, Woollen, Boyd, Kemper, and Rowland.

DR. G. W. H. KEMPER, of Muncie, read a paper on

ANGEL-WING DEFORMITY,

based on his own observations as pension examiner. He thought the disease, which is in the nature of paralysis of the shoulder, is caused by overwork and lack of proper diet, and he recommended the use of electricity in treating it. A man so afflicted does not have the free use of his arm, as he can raise it only to a horizontal position.

DR. L. B. WOOLLEN, of the Switzerland County Society, submitted a paper on

ADENIA, OR HODGKIN'S DISEASE,

in which he narrated a case, treated by him years ago, of a man who came of a scrofulous family and first suffered from enlargement of the glands of the neck, which spread to other glands. He found that croton oil, externally applied, was the most satisfactory remedy to relieve the pain, although the disease is incurable.

AFTERNOON SESSION.

DR. GEORGE J. COOK, of Indianapolis, read a paper on *Puritus Ani*.

PUBLICATION OF THE TRANSACTIONS.

The committee appointed to consider the matter of publishing the Transactions of the Indiana Medical Society in the *Indiana Medical Journal*, reported the following resolution for adoption by the Society:

Resolved, As the sense of this Society that the Select Committee should proceed at once to prepare the draft of a contract with the proprietor of the *Indiana Medical Journal* for issuing, for the next ensuing year, the Transactions of this Society in his journal. *Provided*, that the expense shall not exceed sixty cents per capita of the entire membership of this Society.

On motion, the matter was laid over until the next annual meeting of the Society, the auxiliary societies to act upon the proposition in the meantime.

THE COMMITTEE ON ETHICS

reported in the case of Dr. W. W. Vennedges's appeal from the Tippecanoe County Medical Society, that the action of the Society be sustained. In the case of Dr. E. T. Mendenhall, of the Henry County Medical Society, the Committee reported that no action can be taken, as his case had not been presented in legal form. The report was adopted.

DR. JOSEPH EASTMAN, of Indianapolis, read a report of *Four Cases of Ovariotomy*, and DR. J. F. HIBBERD read a paper on *Post-partum Hemorrhage*.

EVENING SESSION.

THE PRESIDENT, DR. S. E. MUNFORD, of Princeton, then delivered his

ANNUAL ADDRESS,

his subject being a *A Question in State Medicine*. He said: It has been the custom to charge the faulty edu-

cation of the profession in this country to the medical schools. From the largest in the land, to those of exiguous classes and light equipments, these institutions are not guiltless. They have been too much possessed by our national impatience and hurry, and have practically allowed students to determine the time they should study, and what should be the standard of requirements.

This Society and its auxiliaries are educating centres in the interest of the profession and for the good of the people. One State, and some local societies in this country have established a standard of literary attainments for those who desire to enter the profession, and make it obligatory upon their members to receive no one under their care who shall not possess the certificate of a board of examiners setting forth their fitness to engage in the study of medicine. The perfection of the organization of this body, and its admirable *ésprit du corps* render a measure of this kind easily practicable to it, and I trust we shall have such as a part of our organic law at an early day. Such a restriction of medical pupilage could not fail to exert an immediate salutary influence.

In conclusion he said: In presenting this subject for your consideration, I have endeavored to show the following points: That vicious practices in medical schools began in the remote past, and have been fostered in our day by competition, and by the rush and haste which are characteristic of our energy; that the fundamental cause of incompetency in the medical profession in this country is primal illiteracy; that the intelligent comprehension and use of an art which rests upon science is not possible to the ignorant; that the presence in the profession of those who have not the educational attainments essential to intelligent citizenship is injurious beyond all calculations of the interests of medicine, and is a peril to society; that the remedy is a better scholarship, and its application is largely with the profession. With all there is to regret as to the educational standard of medicine, there is just cause in this day for congratulation. There is a general awakening in favor of reform, and if we read aright the signs of the times the next decade will mark a greater advancement in the interests of our profession than has been wrought in thrice that period of the past. The medical press, the medical schools of the better class, and the general sentiment of the profession seem to favor measures which have for their object the improvement of the educational qualifications of the American doctor. While we invoke and await the aid of the law to regulate the practice of medicine in the interest of the people, let us commend our cause to society by unceasing internal efforts for reform.

WEDNESDAY, JUNE 11TH—SECOND DAY.

DR. A. J. MILLER, of Paris, Ill., read a paper with especial reference to the

WORK OF THE ILLINOIS MEDICAL ASSOCIATION.

He said the tendency was to elevate the standard of medicine in his State, despite the defects and inability to obtain needed legislation. Protection against the mountebanks and charlatans, he thought, was essential to the welfare of the profession.

DR. D. A. MOSS, of the Oxford Retreat, and a member of the Ohio Medical Society, said that the same difficulties existed in Ohio, touching legislation, and it seemed impossible to get a bill through the legislature of any consequence. One reason of this was that so many men prepared bills, and the supporters of one usually antagonized all others.

In the absence of DR. H. V. SWERINGER, of Fort Wayne, his paper on *Post-partum Intrauterine Injections of Carbolic Acid*, was referred to the Committee on Publication.

DR. W. H. MYERS, of Fort Wayne, read a paper on *Puerperal Pyæmia*.

DR. J. R. WEIST, of Richmond, read a paper entitled

MALPRACTICE SUITS; CAN THEIR FREQUENCY BE LESSENED?

He asserted that every action for damage for alleged malpractice was encouraged by some rival of the defendant in the medical profession. Many medical men of property, he said, would not take a case in surgery, knowing that they would run the risk of a suit for damages, provided their operation was unsuccessful. He cited numerous instances of physicians losing thousands of dollars in defending malpractice suits before ignorant juries. In Henry County alone, judgments had been entered against physicians falsely accused of malpractice to the amount of $14,000. He submitted a resolution passed by the Wayne County Medical Society, urging the passage of a bill drawn by State Senator Foulke, providing in the trial of an issue for the appointment by the court of one or more expert witnesses, who shall be required to give testimony and shall be paid the same as ordinary witnesses. Such a measure, Dr. Weist thought, would be of inestimable value to physicians in defending suits brought by irresponsible and dishonest persons simply for gain.

DR. E. F. HODGES, of Indianapolis, read a paper on the same subject, in which he took the lawyers to task for encouraging the bringing of malpractice suits. He regarded them as largely responsible for the trouble caused to reputable physicians.

DR. P. H. JAMESON said that a malpractice suit had never been prosecuted successfully in Marion County. He attributed this to the fact that the physicians had protected one another.

DR. F. J. VAN VORHIS defended the legal profession against the attack. He was of the opinion that the passage of the Foulke bill might accomplish good results. The further consideration of the matter was postponed, pending the report of the Committee on Legislation.

THE FINANCE COMMITTEE

reported that the accounts of the Secretary, Treasurer, and Committee on Publication, had been examined and found to be correct, and recommended that $100 be allowed the Secretary, $50 to the Publication Committee, and $25 to the Treasurer.

DR. G. V. WOOLLEN objected to the report, saying that the Society should know something more about the finances.

The report was referred back to the Committee, with instruction to hear Dr. Woollen's objections.

The Report of the

COMMITTEE ON HOSPITALS FOR INSANE WOMEN,

by DR. MARY F. THOMAS, of Richmond, was received.

The Committee was appointed at the annual meeting of the Society, in May, 1880, to examine the reports of hospitals for insane women, where women physicians have been employed. Dr. Thomas says: "These reports have been encouraging, and the expression of those immediately connected with them so satisfactory, that it merits a continuance of the practice so auspiciously begun."

The COMMITTEE ON NOMINATIONS reported the following list of

OFFICERS FOR THE ENSUING YEAR:

President.—J. H. Woodburn, M.D., of Indianapolis.
Vice-President.—James A. Grigg, M.D., of Fort Wayne.
Secretary.—E. A. Elder, M.D., of Indianapolis.
Assistant Secretary.—W. H. Lopp, M.D., of Columbus.
Treasurer.—G. W. H. Kemper, M.D., of Muncie.

AFTERNOON SESSION.

DR. S. S. BOYD, of Dublin, read a paper on *Medical Legislation*.

DR. GEORGE W. KNOLAND, Chairman of the Committee on the subject, reported *A Bill to Regulate the Practice of Medicine*.

Drs. Weist, Hodges and Van Vorhis were appointed a Committee to further the passage of an Act to govern the courts in the matter of *Expert Testimony*.

MEDICAL LEGISLATION.

DR. J. F. HIBBERD presented the following resolution:

Resolved, That it is the sense of this Society that the time has arrived when the members should exert their influence, singly and collectively, to secure the passage of a State law requiring of all persons seeking to become practitioners of medicine, that they shall be thoroughly educated in the elementary branches of medical science, and such education should be ascertained by a board of medical examiners, no member of which shall have any official connection with any institution of medical education. Adopted.

DR. HOBBS moved that all the papers now before the Society on medical legislation be referred to a select committee, who should be empowered to prepare the necessary points for a bill to be acted upon by the next Legislature. The president named as the Committee, Drs. Wilson Hobbs, Joseph G. Rodgers, and J. H. Woodburn.

DR. J. L. THOMPSON read a paper on *Asthenopia*.

EVENING SESSION.

DR. THEO. L. WAGNER, of Indianapolis, read a paper on

SMALLPOX AND THE PEST-HOUSE.

He said he had come to the conclusion that while we have advanced in the quality of the virus by using the bovine exclusively, we have retrograded in the manner of vaccination. Vaccination should be practised in at least two abrasions in different parts of the body, and be repeated until the virus ceases to take effect. Touching vaccine lymph, our laws, or rather our lack of laws on this subject, puts us all at the mercy of vaccine producers, whose honesty is our only reliance.

DR. J. W. MARSEE, of Indianapolis, gave a demonstration of a method of

TREATMENT OF FRACTURES OF THE LEG.

He erected a tripod about nine feet high on the stage. He then took a colored man, and, after placing him on a cot, he raised him by means of a pulley, using straps, head-rest, etc., to hold the body at any required height. He then showed how this could be accomplished by means of the ordinary appliances to be found about any house, in case a physician should be called to the country. In this demonstration he used an ordinary piece of wood as the bar, a strip of cloth for the head-rest, and a pair of carriage lines for straps. Having raised the body to a sufficient height, he proceeded to show how to put on the bandages, going into all the details, from the proper adjustment of the parallel plasters to the binding of the last cotton bandages. The body was then lowered and raised in different positions to demonstrate the methods of handling the patient.

THURSDAY, JUNE 12TH—THIRD DAY.

Papers were presented by Drs. H. I. Raymond, on *Antiseptic Treatment of Gunshot Wounds;* B. Wallace, of Franklin, on *Two Cases of Foreign Bodies in the Trachea;* T. J. Dills, of Fort Wayne, on *Intraocular Tumors;* and J. S. Arwine, of Columbus, on *Race Poison*.

The Committee on Legislation, by resolution, was instructed to provide in the bill to be presented to the next legislature that no physician shall be appointed upon the Board of Medical Examiners, who is not endorsed by the Indiana State Medical Society.

A SCHOOL OF PHARMACY.

The following was unanimously adopted:

The Trustees of the Purdue University having established a school of pharmacy in connection with the University, and recognizing the great need of educated and skilled pharmacists in order to enable the educated physician to successfully encounter disease, we hereby express our pleasure and approval of the action of the Trustees and pledge them our sympathy and support.

The customary vote of thanks was tendered to the retiring officers, and the Society then adjourned to meet in Indianapolis, on the second Tuesday in May, 1885.

MICHIGAN STATE MEDICAL SOCIETY.

Nineteenth Annual Session, held at Grand Rapids, June 11 and 12, 1884.

(Specially reported for THE MEDICAL NEWS.)

WEDNESDAY, JUNE 10TH—FIRST DAY.

MORNING SESSION.

THE meeting was called to order by THE PRESIDENT, DR. A. F. WHELAN, of Hillsdale. An address of welcome was delivered by the Hon. C. E. Belknap, Mayor.

The roll was then called by Secretary Ranney, and 109 members answered to their names.

The reports of the Secretary and Treasurer were then read. The *balance* in the treasury was $1050, exclusive of about $600 collected at this meeting.

PROF. DONALD MACLEAN, of Detroit, Chairman of

the Committee on Surgery, reported four surgical cases which had come under his care.

A well-digested, carefully written essay by Dr. Samuel P. Duffield, of Dearbornville, was then read on *Expert Testimony and Compensation*.

Afternoon Session.

Dr. C. J. Lundy, of Detroit, read a paper entitled

the dry treatment of chronic suppurative inflammation of the middle ear.

All knew that the disease was attended with danger, and that many had seen examples of caries and necrosis of the temporal bone, mastoid abscess, meningitis, cerebral abscess, or death which occurred as the result of a neglected suppurative otitis media. Therefore any system of aural therapeutics which the better enabled us to control and cure this affection was a great boon. Before beginning the use of powders, all remediable complications must be removed. If aural polypus or granulations be present, they must be removed or destroyed; and so it was also with removable pieces of necrosed bone in the mastoid or elsewhere.

The advantages which the dry treatment of chronic suppurative otitis media seemed to offer were: (1) The constant medication of the parts; (2) the thorough and continuous disinfection of the ear as well as the destruction of microörganisms; (3) the absorption of the discharges and protection from their irritating properties; (4) protection from atmospheric influences. It could not be claimed that powders should be used to the exclusion of remedies in other forms, and they were contraindicated at times. In certain cases they proved a failure, and sometimes did harm instead of good. While no definite plan could be laid down for the management of individual cases, yet some rules could be formulated for our guidance in a general way.

The so-called dry treatment would seem to be contraindicated under the following circumstances:

First. When the discharge is so profuse that the powder becomes supersaturated before it has had time to exert any beneficial influence. *Second.* When granulations or polypi exist, the dry treatment should not be employed until these bodies have been destroyed or removed; although powdered boracic acid would cause absorption or destruction of these in a few cases. *Third.* When the disease is complicated by caries or necrosis of the temporal bone. *Fourth.* When mastoid abscess is present or suspected. *Fifth.* When there is good reason to suspect the presence of meningeal or cerebral complications.

The remedies which might be used in the form of powder were numerous, but the writer had confined himself to the use of a few. He had found boracic acid to meet the indications in a majority of cases. When absolutely free from impurities it was a valuable remedy. It was difficult to get a preparation that had no irritating properties. Many failures to cure were attributed to want of therapeutical value of the medicine, whereas the impurities in the remedy were at fault. He had found Wyeth's boracic acid pure and free from irritating properties.

Boracic acid and resorcin—seven parts of the former and one of the latter—formed a valuable combination. Resorcin was too soluble to be used alone. Bismuth and the perchloride of mercury were valuable, especially when eczema of the auditory canal or dermatitis of the canal existed. Astringents could be combined with boracic acid if desired.

Before using these powders, the ear should be thoroughly cleansed. This was a matter of great importance. By means of a powder-blower, some of the powder should be blown into the deeper portions of the auditory canal, and even into the tympanic cavity, after which the canal should be more or less completely filled with the powder. After a lapse of one, two, or more days, according to circumstances, or when the powder becomes moist, it should be removed, the ear should be again thoroughly cleansed, and the powder reapplied. Cases were reported showing some very remarkable cures from the use of remedies in dry form, especially from boracic acid.

President Whelan then called Vice-President Tupper to the Chair, and read his

annual address,

on *Developments of Medical History, Science, and Art*, closing with an appropriate tribute to the memory o Drs. James H. Jerome and William Brownell, deceased.

Dr. C. George, of Ann Arbor, read a lengthy paper giving the history of the use of *Large Doses of Turpentine in the Treatment of Diphtheria*, and his personal experience with it.

Dr. H. O. Walker, of Detroit, read a valuable paper on *Exploration of the Male Urethra*, exhibiting instruments to facilitate the same.

Prof. A. B. Palmer, of the University, read a paper on

prostatic hypertrophy and urinary obstruction; its treatment without catherization,

which, from the simplicity, and, to many, the novelty of the method, attracted particular attention.

After referring to the frequency of prostatic enlargement in advanced life, and the occurrence of what specialists call the "catheter period," which means a period of such obstruction to the passage of the urine in which the bladder is not completely emptied, an irritation of the urinary organs of a somewhat decided character occurs, and which also implies that from that time onward, the catheter must be a constant companion, and one likely to be brought into frequent use, and after further referring to the great unpleasantness and not unfrequent dangers of its introduction, the "catheter fever," and the still more frequent shock, the method of procedure in the management of cases was described as follows:

The urethra is to be filled with urine as in an effort at micturition. The penis is then grasped by the hand of the patient and the urethra is pressed upon so as to interrupt the flow; and then by straining as in the attempt to forcibly empty the bladder, the distention of the urethra is produced. This distending pressure is gentle, steady, diffused, and painless, and may be applied and sustained at will; and in a majority of cases, if daily repeated for a time, and if it is done thoroughly, and especially if commenced at an early period of the obstruction, it will overcome this form of stricture effectually, and without irritation or danger. A case, as a specimen of many others, was given in detail, as illustrating the efficiency of the measure.

The paper concluded with the statement that from sufficient experience, the efficiency and value of the method had been demonstrated, and it was strongly commended to the attention of the profession.

In compliance with a resolution previously made by Dr. Pratt, and adopted by the Society, the President appointed a

COMMITTEE TO NOMINATE OFFICERS

for the ensuing year, except the President. The committee was composed of Drs. Wm. Brodie, H. McColl, S. H. Clizbee, G. K. Johnson, and E. P. Christian.

DR. J. H. CARSTENS, of Detroit, read a paper on *Sterility in Women*.

THURSDAY, JUNE 12TH—SECOND DAY.

MORNING SESSION.

REPORT OF A CASE OF PERINEPHRIC ABSCESS,

by DR. GEO. K. JOHNSON, of Grand Rapids, was next read. This was a history of a man twenty-two years of age, whose illness, at first, was marked by the symptoms of typhoid fever, but they soon partially abated and an indefinite ailment, characterized by weakness, want of appetite, loss of flesh, feeble pulse, cachectic fever, and pain in the left iliac and lumbar region, led him again to seek advice. Pain in the left costo-iliac space had come on, and was increased by pressure; a feeling of weight in left flank and left upper abdomen was complained of, but no pain in genital tract or groin. Urine voided frequently, loaded with pus, but without blood, mucus, or casts. Left half of abdomen distended with a fluctuating tumor which was easily defined. A hypodermic needle passed into the tumor withdrew a drachm of pus and confirmed the diagnosis. The body forces were fast waning, and the danger that the cyst would rupture and pour its contents into the cavity of the abdomen was imminent; it was decided at once to aspirate the tumor. Passing the needle at the external margin of left rectus, two inches below the level of the umbilicus, eighty-four ounces of pus were removed; within a few hours relief came, fever left, and pain vanished. On the second day the temperature of the patient reached 100° F. in the morning, and 104° in the evening. On the fourth day the temperature was 99½° in the morning, and 104½° in the evening, when it reached its climax; the patient having, though restless, suffered no pain or swelling of the parts since aspiration.

Six days after the aspiration, some fulness appeared over the site of the tumor, and a few days later there was found to be considerable reaccumulation of pus, but the discharge by the urinary conduits was so free that no further accumulation took place, and all tumefaction slowly but steadily disappeared. Three months after aspiration the patient seemed entirely well; appetite, strength, flesh, and spirits, were fully restored. The urine was normal, and all traces of the tumor were gone. The author closed his paper with a comprehensive review of the literature of perinephric abscess.

DR. E. P. CHRISTIAN then read a paper on *Placenta Prævia*.

The Committee on Nominations then rendered their report, which recommended the following

OFFICERS FOR THE ENSUING YEAR:

Vice-Presidents.—Drs. J. Perkins, of Owosso; J. M. Cook, of Muskegon; Gordon Chittock, of Jackson; Carl Brumme, of Detroit.

Secretary.—Dr. Geo. E. Ranney, of Lansing.

Treasurer.—Dr. A. R. Smart, of Hudson.

Members of Judicial Council (for three years).—Drs. F. K. Owen, of Ypsilanti; C. V. Tyler, of Bay City; Hugh McColl, of Lapier.

DR. WARD moved the adoption of the report.

DR. H. B. SHANK moved to amend by laying the report on the table.

The amendment was lost, and the original motion was adopted.

The Society then proceeded to ballot for President. The whole number of votes cast was 196, of which Donald Maclean received 126; S. S. French received 63; scattering, 6.

The President said that DR. DONALD MACLEAN, having received a majority of all the votes cast, was elected President.

DR. G. K. JOHNSON said that, as in the minds of some the Society should be reorganized, he offered the following:

Whereas, as it appears that the present organization of the Michigan State Medical Society fails to give general satisfaction,

Resolved, that the Chair appoint a committee of five to take into careful consideration the entire matter and report at the next annual meeting. Carried.

DR. MILLS, of Port Huron, invited the Society to hold its *Next Annual Meeting* at Port Huron.

DR. H. B. SHANK moved to amend by substituting Lansing in place of Port Huron. The amendment was lost, and the original motion was adopted.

DR. CHARLES SHEPARD read a report on *Several Cases in Gynecological Practice*.

AFTERNOON SESSION.

DR. A. W. NICHOLS, of Greenville, read a paper on *Nasal Catarrh*.

DR. EUGENE SMITH, of Detroit, read a paper on

GRANULATED LIDS,

and related a case in which he had used jequirity with good effect. He uses a three per cent. solution, and applies it two or three times a day, for three or four days, and then follows with boracic acid. He thinks this remedy is well adapted to old chronic cases in which there is no purulent secretion.

DR. R. J. KIRKLAND, of Grand Rapids, read a paper on *Chronic Catarrhal Otitis*.

A paper by DR. A. R. SMART, of Hudson, on *Therapeutics of Dysmenorrhœa*, was read by title and referred.

DR. WADE, of Holly, read a paper on *Uterine Displacements*.

DR. DUFFIELD moved that when the Society adjourns, it does so to meet on the Second Wednesday of June, 1885. Carried.

THE PRESIDENT appointed the following committees:

To Report on Reorganization of the Society.—Drs. G. K. Johnson, A. W. Alvord, H. McColl, L. Connor, W. F. Breakey.

Committee on Legislation.—Drs. Foster Pratt, Wm. Parmenter, C. V. Tyler, Augustus Kaiser, A. W. Smart.

Over two hundred physicians were in attendance, up-

wards of eighty per cent. of whom were elected members at this meeting.

The Society transacted considerable miscellaneous business of a personal and local character during the session, and the meeting was the largest gathering of the physicians of Michigan ever held.

MINNESOTA STATE MEDICAL SOCIETY.

Sixteenth Annual Meeting, held at Stillwater, June 19 and 20, 1884.

(Specially reported for THE MEDICAL NEWS.)

THURSDAY, JUNE 19TH—FIRST DAY.

THE Society was called to order by THE PRESIDENT, DR. LINCOLN, of Wabashaw; about one hundred and twenty-five members being in attendance.

A COMMUNICATION FROM THE NEBRASKA STATE MEDICAL SOCIETY

was received, containing the following provisions:

"The Committee on Foreign Correspondence shall consist of one duly accredited representative (a member of this Society) for each State and Territorial Medical Society. They shall receive and review the *Transactions* of the Societies which they represent, and, through their Chairman, the Corresponding Secretary shall present annually a report of the advances in medicine made by said societies. They shall also report such other matters as their societies may wish to communicate to the Nebraska State Medical Society.

"It shall be the duty of the representatives of any foreign society to communicate all advances in matters medical and governmental made by said Society in the year just past, as well as all matters of whatever kind his society may wish to be brought to the notice of the Nebraska State Medical Society."

In accordance with this implied request, DR. BLACKMER, of Albert Lea, was appointed the representative of Nebraska in the Minnesota Medical Society.

THE ADDRESS OF THE PRESIDENT,

DR. LINCOLN, of Wabashaw, was an appeal to physicians to promulgate the doctrines of hygiene and preventive medicine. It discussed the physiological effects of alcohol, and dealt with inebriety as a disease, and with the relations of alcoholism to heredity. The members of the Society were urged to study the problems involved in these subjects, and to record and preserve all facts within their experience which may aid in their solution.

AFTERNOON SESSION.

MISCELLANEOUS BUSINESS.

DR. HUNTER, of Minneapolis, offered a resolution to the effect that the chairmen of committees shall act as a committee whose duty it shall be to examine all papers to be presented at the annual meeting, and to decide which shall be read and discussed; and that the Corresponding Secretary shall furnish each member with a list of such papers at least a month before the meeting. The resolution was unanimously adopted.

DR. LEASURE, of St. Paul, offered a resolution which provided for a committee of three to report at the next meeting such measures as would facilitate and improve discussions and the working methods of the Society.

THE COMMITTEE ON PRACTICAL MEDICINE

made a report, of which the most interesting feature was the description by Dr. Leasure of a case of acute cough with fever, accompanied by expectoration of a quantity of phosphatic pulmonary concretions; the patient recovered.

DR. DUNN, of Shakopee, now in Vienna, was appointed a delegate to the International Medical Congress at Copenhagen.

THE REPORT OF THE COMMITTEE ON MEDICAL EDUCATION

deprecated the multiplication of medical colleges, and urged the appointment of boards to examine all physicians without exception.

To a question as to what good had been accomplished by the

STATE BOARD OF EXAMINERS,

DR. MILLARD replied that he had the addresses of two hundred and twenty persons practising medicine who have left the State since the enactment of the law, and that there are but twelve within its limits who have not yet complied with its requirements. A case is now pending in the Supreme Court to test the constitutionality of the law. Dr. Millard said that the Board will protect the profession and endeavor to raise the standard of professional excellence, and asked for support and countenance.

DR. HUNTER presented the

REPORT OF THE COMMITTEE ON SURGERY,

which related chiefly to visceral surgery, and to the management of wounds. Dr. Staples having advocated the treatment of hip-joint disease by leather splints.

DR. BAUER, of St. Louis, addressed the Society upon the subject of that disease; its pathology and treatment. He denied emphatically its diathetic nature or origin, affirming that its cause in almost every case is traumatism. He urged absolute rest, immobility, and, when indicated, tenotomy, as the only rational treatment; extension and counterextension being wholly useless and uncalled for.

Hernia and herniotomy were discussed, and operations for radical cure described.

DR. AYRES, of Omaha, Delegate from the Nebraska Society, reported a case of *Wound of the Internal Carotid* by broken glass. The accident occurred in the street, where Dr. Ayres tied the common carotid, the patient lying on the sidewalk. Recovery ensued, with some facial paralysis.

The Society was entertained at the Sawyer House in the evening, a banquet being tendered by the Washington County Medical Society.

FRIDAY, JUNE 20TH—SECOND DAY.

MORNING SESSION.

DR. CLARK, of Stillwater, for the

COMMITTEE ON OBSTETRICS,

presented a report. He discussed the use of ergot and of anæsthetics in labor, the aseptic management of the puerperal state, and intrauterine irrigation. An animated discussion followed. Drs. Dunsmoor, Hunter, and French expressed grave doubt as to the safety of

intrauterine injections, and cases were cited illustrative of their danger. Preference was given to mopping out the uterine cavity with cotton covered with boracic acid or iodoform. Dr. Stone defended the use of injections, and advocated the administration of chloroform in labor, especially when organic cardiac disease exists. Dr. Bauer condemned bichloride uterine or vaginal injections, and would use chloroform freely except in anæmic cases. Dr. Lincoln described a case in which, soon after delivery, a chill occurred, followed by a temperature of 106° The patient was in a shanty on a prairie, where not only irrigation, but even efficient nursing, was unattainable. Twenty grains each of quinia and potassium bromide were administered, and in a few hours the temperature fell to 100°; no other treatment was required. Dr. Lincoln remarked that if irrigation had been resorted to in this case, it would have been credited with the recovery.

Various committees presented reports, which were read by title. That of the Gynecological Committee dealt with cleanliness, the calibre of the urethra, trachellorrhaphy, and tubercle of the peritoneum.

DR. OWENS offered a resolution endorsing the State Examining Board, and pledging the support of the Society, which was unanimously adopted.

A request from the Women's Christian Temperance Union, that a committee be appointed to investigate the subject of Alcoholism and Heredity, was placed on file.

AFTERNOON SESSION.

DR. FULTON, of St. Paul, Chairman of the Committee on Ophthalmology, read a paper upon *Functional Affections of the Eye.*

DR. ABBOTT, of Minneapolis, urged the importance of the general practitioner qualifying himself to recognize and treat certain diseases of the eye (*e. g.*, iritis), the diagnosis of which is often made only by a specialist, and too late for successful treatment.

THE ELECTION OF OFFICERS

being in order, resulted as follows:

President.—Dr. J. B. McGaughey, of Winona.

Vice-Presidents.—Drs. F. A. Dunsmoor, of Minneapolis; W. H. Pratt, of Stillwater; and C. A. Wheaton, of St. Paul.

Treasurer.—Dr. S. B. Sheardown, of Stockton.

Recording Secretary.—Dr. C. H. Boardman, of St. Paul.

Corresponding Secretary.—Dr. A. F. Ritchie, of Duluth.

Censors (*for three years*).—Drs. J. C. Rhodes and V. Smith.

After the usual complimentary resolutions, the Society adjourned, to meet in St. Paul on the third Thursday in June, 1885.

NEW HAMPSHIRE MEDICAL SOCIETY.

Ninety-fourth Annual Meeting, held at Concord, June 17 and 18, 1884.

(Specially reported for THE MEDICAL NEWS.)

TUESDAY, JUNE 10TH—FIRST DAY.

The Society was called to order by THE PRESIDENT, DR. JOHN W. PARSONS, of Portsmouth.

After the usual appointment of special committees by the Chair, the Secretary read the report of the meeting of the Council, which was approved by the Society.

THE PRESIDENT, DR. J. W. PARSONS, spoke at some length on

THE IMPORTANCE AND WELFARE OF MEDICAL ASSOCIATIONS, ESPECIALLY THE NEW HAMPSHIRE MEDICAL SOCIETY.

He spoke of the influence of associations in advancing the interests of every avocation, and upon the progress of civilization in general, and although much had been accomplished he looked for still greater achievements in the future. Medical associations have their portion of this work to perform, and although they do not make discoveries, they stimulate the members to greater exertions and turn their minds into new and broader channels of thought and investigation.

He then enjoined upon the members that care should be taken not to receive into their offices or admit to their patronage, young aspirants for the medical profession, who fail to exhibit evidence of a proper preparatory education. The doors should be wide open to the educated, but carefully guarded against the entrance of the ignorant, even at the risk of occasionally excluding a brilliant mind.

DR. C. P. BANCROFT, Superintendent of the New Hampshire Asylum, read a paper entitled

INQUIRIES INTO THE CAUSES OF INSANITY, WITH ESPECIAL REFERENCE TO PREVENTION AND TREATMENT.

In opening his paper he discussed the history of insanity during the last fifty years, and made reference to the superstition regarding it in early times. As an outcome of a scientific study of the subject, it has been proved to be as specific a disease as any other morbid condition. Mental disease is governed by the same laws that apply to diseases in general. There is a close relationship between constitutional diseases like phthisis, epilepsy, chorea, etc., and insanity in the same individual. This diathesis at one time may develop as insanity, and at another time as some other disease. He believed that a close relationship exists between chronic insanity and constitutional disease.

Acute mania, in many instances, results from defective habits of life and over-taxing the mental powers. In the New Hampshire Asylum about seventy-five per cent. are chronic cases, which the reader regarded as resulting from hereditary causes. This class, as a rule, is incurable. Of the acute cases, as many recover under practical treatment as get well from other acute diseases.

The reader did not believe that insanity was necessarily transmitted from parents to children, but that oftentimes other constitutional diseases appeared instead. On the other hand, diseases like scrofula, phthisis, syphilis, etc., may not appear in children as such; but other organic changes in the nerve-centres, producing chorea, epilepsy, insanity, etc. Any cause which changes the cell structure of the brain or nerve-centres may produce the disease. This is illustrated in disturbances of the motor nerves which result in chorea and epilepsy. Similar disturbances occurring in the intellectual portion of the brain result in insanity. These hereditary tendencies were implanted in the very

foundation of the physical structure of the individual, even though they did not appear for many years afterwards; in some instances a generation or two were passed. The latter is often the case in intemperance, phthisis, etc.

So long as children are born whose parents are afflicted with these constitutional diseases, so long will they be found in every community. If physicians would point out intelligently to every community the impending danger of such unions, much would eventually be accomplished in preventing such results as are now witnessed everywhere. When such constitutional tendencies exist, the physician could do much to avert a manifestation of these diseases by advice to the subject relative to methods of living, work, climate, etc.

DR. EDWARD O. OTIS, of Exeter, read a

REPORT ON SURGERY,

in which he discussed the various methods of antiseptic treatment and antiseptics. He especially called attention to the methods of applying the first bandage with reference to drainage. The elastic bandage was next taken up, and statistics given relative to the results of its use. He reported 55 cases of removal of the breast, in 47 of which the axilla was opened and cleared of enlarged glands. The dressing first applied was allowed to remain until perfect, or nearly perfect healing had resulted in 39 of these cases. In 49 cases of knee-joint resection, the primary bandage was not removed in 34 until nearly healed. Other equally remarkable results were given.

The surgical treatment of pleurisy with effusion, and of empyæma, was next considered. Paracentesis was recommended in the form of a permanent opening, with proper antiseptic precautions. Dr. Cabot's method was given, and his trocar exhibited.

DR. E. S. BERRY, of Dover, read a paper entitled,

RESPIRATORY IRRIGATION IN THE TREATMENT OF EMPYÆMA.

The reader endeavored to prove the value of respiratory irrigation over Listerism, showing the value of traction in producing expansion of the lung, and to illustrate the worth and convenience of this method of treating empyæma in private practice. He discussed somewhat the history of the treatment of this disease, by tapping the chest prior to 1850, when Dr. Bowditch advocated paracentesis so strongly. He believed that Listerism was a great advancement in the treatment of this disease, and recognized in connection with it the method of traction advocated by Dr. Cabot of Boston. He reported a case treated by respiratory irrigation, in which a rubber tube was made to enter the pleural cavity and bound firmly in place, with the other end terminating under a solution of thymol. The solution was changed whenever it became turbid. By this method the cavity was irrigated by each respiration as the solution passed in and out through the tube. The traction mentioned was produced by the constant weight of the water in the tube. The patient made an excellent recovery.

The advantages of this treatment the reader summed up as follows: *First.* That septic changes were completely prevented by this method. *Second.* The great value of traction in bringing about an expansion of the lung. *Third.* The ease and facility with which fibrin, clots, etc., were washed from the pleural cavity. *Fourth.* Its advantages over Listerism, and the less expense and attention required in managing the case.

DR. M. C. LATHROP, of Dover, read a paper on

MOTHERS' MARKS.

In the supposed cases of mothers' marks he discussed the opinions of many prominent persons who entertained this popular view of the subject, and who believed that the pregnant woman could receive impressions upon her nervous system which, through reflected action, produced malformations or disfigurations in the child. He believed the theory to be a delusion, notwithstanding Carpenter and Dalton had endeavored to sustain it by theories admitting its possibilities. The whole foundation of such a belief rested upon the difficulties of otherwise accounting for certain congenital defects, which the imagination associated with certain events, or objects, because coincident. Physiology, itself, protested against such a view of the subject. The only connection from the first between mother and child was one of nutrition; aside from that they were distinct individuals. That this avenue was sufficient for conveying the mental shocks or impressions of the mother was very absurd. He believed that hereditary defects, alone, were sufficient and rational explanations of the various conditions usually classed as mothers' marks.

DR. I. G. ANTHOINE, of Antrim, read a paper on

AIDS IN OBSTETRICS.

He regarded chloroform as standing first in the list. Its advantages over ether were many. Its effect was rapid; it was not necessary to produce unconsciousness; it caused less excitement, and was in every way preferable. His method of administering it was from a folded napkin placed in the palm of the hand. He would never give it to the extent of complete anæsthesia. The efforts of the patient were of as much avail as if chloroform had not been given. He had given it about one hundred times and seen no bad results to either mother or child. The reader gave an illustration to show that the os was much quicker dilated by its use even in the earlier stages of labor.

Forceps were of great aid when there was danger of laceration of perineum. When the uterine pains cease it is much better to apply the forceps than to give ergot.

DR. C. R. WALKER, of Concord, read a paper on

ANTISEPTIC SURGERY.

The author concluded that for general purposes carbolic acid or the bichloride of mercury solution was the most feasible for ordinary work. Even when unable to obtain any of the specially prepared dressings, he thought that, aided by the pure air of the country, one should not despair of keeping a wound aseptic by means of cotton or any thickly applied clean absorbent material. He thought that accurate coaptation of surfaces, firm compression and rest were the real secrets of much of the success of all dressings, antiseptic or otherwise. Finally, he claimed that we imperilled our results by too frequent dressings, declaring that the laws governing the strict use of antiseptic materials should govern also the change in all simpler dressings.

WEDNESDAY, JUNE 11TH—SECOND DAY.

DR. EZRA MITCHELL, of Lancaster, read a paper on

GYNECOLOGY,

in which he reported twenty-three cases of lacerated perineum and cervix operated upon by Dawson's method. In eight cases the operation was performed on both the cervix and perineum at the same time, and took, upon the average, about thirty minutes. The advantages claimed for this method are: 1. Much better results; 2. Simplicity of operation, by which any physician of ordinary ability can operate. The cases were reported in detail, and showed remarkably good results.

DR. MARY DANFORTH, of Manchester, presented a

REPORT UPON OBSTETRICS.

This paper was a long and exhaustive one on obstetrical practice in New Hampshire, and embraced a large amount of valuable statistical matter obtained by correspondence with nearly all of the physicians in the State.

The following were then elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. John Wheeler, of Pittsfield.

Vice-President.—Dr. Geo. A. Crosby, of Manchester.

Secretary.—Dr. G. P. Conn, of Concord.

Treasurer.—Dr. D. S. Adams, of Manchester.

Executive Committee.—Drs. C. R. Walker, of Concord; George D. Towne, of Manchester; J. R. Kimball, of Suncook.

COLORADO STATE MEDICAL SOCIETY.

Thirteenth Annual Session, held at Denver, June 17, 18, and 19, 1884.

THE fourteenth annual session of the Colorado State Medical Society was called to order by THE PRESIDENT, DR. WM. R. WHITEHEAD, of Denver.

DR. G. J. BULL, late of Colorado Springs, presented through Dr. E. C. Rivers, a paper on *Ophthalmology and Otology*, and Dr. E. A. Lee, of Mt. Collins, a paper on *Compound Dislocation of the Ankle-joint.*

The treasurer reported a balance of $77.

DR. H. A. LEMEN, of Denver, read a paper on *Abdominal Section*, in which he presented the record of forty-eight cases operated upon in Colorado.

THE PRESIDENT, DR. W. R. WHITEHEAD, then delivered the annual address, and scientific papers were presented by Drs. Horn, Cox, Lemen, and Solly.

The following were then elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. Hause, of Greeley.

Vice-Presidents.—Drs. Solly, of Colorado Springs; Rogers, of Denver; and Earhart, of Boulder.

Recording Secretary.—Dr. S. A. Fisk.

The Society will meet again next year at Denver.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Special Meeting, June 6, 1884.

THE VICE-PRESIDENT, DR. B. F. BAER, IN THE CHAIR.

DR. WILLIAM GOODELL exhibited specimens of

PYOSALPINX AND HYDROSALPINX.

In the former case, the lady was unmarried and had suffered from pelvic pains and menorrhagia for several years. Last autumn a tumor was discovered by her physician, who deemed it a fibroid of the womb. Early this year her sufferings became so great that she took to her bed. Very large doses of morphia were needed, and septic symptoms now set in. After she had been in bed for several weeks Dr. Goodell was called in to see her. The tenderness of the abdomen was now so great that the examination was made under ether. Even then the diagnosis was obscure, because she flinched and her recti muscles became tense whenever the abdominal wall was pressed upon. A cyst was discovered, but of what nature it was impossible to determine. Dr. Goodell operated on her at his private hospital. The womb was studded with small fibroid nodules; posteriorly, it had an outgrowth as large as a small egg. Closely adherent to the womb, to the pelvic fascia, and to the intestines was a thick-walled cyst of the left ovary as large as the largest orange. The corresponding oviduct was very thick and enlarged to the size of a small sausage. It and the cyst were filled with a very dark purulent fluid, although there was no communication between them. The lower end of the cyst had become necrosed, and was so thinned out that it would very soon have given way at that point. On account of the presence of filroids in the womb, the right ovary was also removed. Attached to the fimbriæ of the oviduct were three very beautiful pedunculated vesicles; while two others, not yet pedunculated, lay in the stroma of the broad ligament. The recovery of the lady was uninterrupted.

In the case of hydrosalpinx, the patient was a widow, aged thirty-seven, who had been sent to him in order to have her ovaries removed. Severe pains began a week before the menstrual flux, culminating during the flow and continuing one week longer, then fading gradually away. For three weeks out of every month she was confined more or less to the recumbent posture, and wholly so during the menstrual week. A tear of the cervix and one of the perineum had been well required by two surgeons, but with no improvement. Dr. Goodell wished her at first to try the rest treatment with message, electricity, and graded muscular movements, for he had repeatedly cured cases of this kind through such a mode of treatment. She was, however, too poor to take this treatment privately and, therefore, was urgent to have her ovaries removed. The operation was performed fifteen days ago, and she is now doing very well indeed. The ovaries, as exhibited, were much enlarged and showed marked follicular degeneration. From this condition Dr. Goodell thought that nothing short of the operation would have cured her. Attached to one oviduct was a delicate vesicle with a thread-like stem of over an inch in length. In view of the frequency with which they are found, he could not but think these vesicles played some *rôle* in the economy, and that they had sometimes a pathological bearing. He had on several occasions met with small post-uterine cysts which burst either spontaneously or under the pressure of an ordinary vaginal examination. Taking anvantage of this fact he had quite recently burst one designedly by bimanual pressure. Such delicate cysts, and also those very movable ones which remained small without increase in bulk, he was disposed to attribute to these vesicles. After bursting, these cysts sometimes refill; one he had known to burst and

refill at least six times before it disappeared. Now small ovarian cysts had, in his experience, thick walls, and, further, they rarely remain small any length of time. Dermoid cysts, on the other hand, often remain stationary for years, but they were generally not very movable, and they also had thick walls.

DR. ALBERT H. SMITH had found these cases of pyosalpinx very difficult of diagnosis. He had been present at an operation by Knowsley Thornton upon a case in which the lesion was double and both tubes and ovaries were removed. Rupture had occurred previously and had been followed by peritonitis. The patient recovered.

DR. B. F. BAER inquired if Dr. Goodell would recommend rupture of cysts arising from the hydatids of Morgagni.

DR. GOODELL would consider it good surgery for the purpose of preventing the further growth of the cyst. He had always found the fluid in small cysts to be unirritating.

DR. ALBERT H. SMITH remarked that Schroeder holds that the fluid of an ovarian cyst is not noxious to the peritoneum. He makes no effort to protect the peritoneal cavity from its ingress during an operation, and yet his statistics show a remarkable success.

In response to a query, DR. GOODELL stated that the dressing of the wound after the operation was glycerole of carbolic acid with the Lister gauze.

NEWS ITEMS.

YELLOW FEVER; PRECAUTIONARY MEASURES.—A number of petitions having been received by the Surgeon-General, M.-H. S., from Tampa, Fla., requesting the establishment of a quarantine station at Tampa Bay, the Mayor was notified on June 23d that "An inspector will be stationed at such point as you may direct, to tide over the emergency through the summer. Regular quarantine buildings cannot be built out of present appropriations."

Similar petitions were also received from El Paso, Texas, and the Collector of Customs at that port was authorized, on June 28th, to appoint a Sanitary Inspector at Nogales, and another at Sasabe, to stop emigrants, baggage, etc., coming from the west coast of Mexico until safe from infection. There is great apprehension felt all along the western border, as Mexico fails to keep up either a quarantine system or look after the sanitary condition of her seaboard towns.

YELLOW FEVER IN MEXICO AND HAVANA.—A recent letter to the State Department, from the U. S. Consul at Guaymas, Mexico, states that three fatal cases of yellow fever had occurred at that place, but that the disease had not yet appeared at Mazattan or San Blas.

Twenty deaths from yellow fever occurred at Havana, Cuba, during the week ending June 28th. The disease is slightly on the increase.

PROGRESS OF THE CHOLERA.—The U. S. Consul at Marseilles has been directed daily to notify this Government, by telegraph, as to the progress of the cholera in France. He reports that the disease has become epidemic at Toulon, and that three cases had occurred at Marseilles, where the population are fast becoming panic-stricken. Precautionary measures are being taken, hospitals established, and preparations made to care for the sick at both places. The latest reports pronounce the disease as true Asiatic cholera. Sanitary Inspectors are to be appointed at the U. S. Consulates in Marseilles, Havre, Paris, Hamburg, Liverpool, and London, for the purpose of giving immediate information relative to the sanitary condition of the places named, and to notify the Department of the departure of vessels, persons, and baggage for the United States.

THE INDEX CATALOGUE OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE, VOL. V.—Dr. Billings has just transmitted to the Surgeon-General of the Army the last corrected proof of Volume V. of the Index Catalogue of the Library of the Surgeon-General's Office, and it will be put to press in a few days. This volume, which begins with "Flaccus" and ends with the subject of "Heart," numbers 1055 pages, and includes 15,555 author titles, representing 5755 volumes, and 12,596 pamphlets. It also includes 8069 subject titles of separate books and pamphlets and 34,127 titles of articles in periodicals, making a total in the five volumes of 50,986 author titles, which represent 30,722 volumes of books and 40,075 pamphlets and 49,552 subject titles of separate books and pamphlets, 183,864 articles in medical journals and transactions of societies, together with 4335 portraits of medical men.

By provision of law, copies of Volume V. can be had for $2 each by any one, on application to the Government Printer, provided the application, accompanied with the money, is sent in before the volume goes to press. As no extra copies are authorized by law, and the number printed is limited to those actually needed by the Surgeon-General for distribution to public libraries and for exchange, medical men desiring to avail themselves of this publication should send their orders to the Public Printer before July 15.

DR. BILLINGS sailed for Liverpool on the Gallia on Wednesday last, *en route* to Copenhagen, to attend the International Medical Congress, as the representative of the Army Medical Department.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 24 TO JUNE 30, 1884.

CLEMENTS, BENNETT A., *Major and Surgeon.*—Ordered to relieve Major Jos. P. Wright, Surgeon, of his duties as Attending Surgeon at the Leavenworth Military Prison, Fort Leavenworth, Kansas. Major Wright, on being relieved, ordered to report to the Commanding General, Department of Texas, for assignment to duty.—*Par 7, S. O. 144, A. G. O.*, June 21, 1884.

HARTSUFF, ALBERT. *Major and Surgeon.*—(Fort Riley, Kansas.) Granted leave of absence for one month with permission to apply for one month's extension. To take effect when his service can be spared.—*Par. 6, S. O. 130, Headquarters Department of Missouri*, June 25, 1884.

DICKSON, JNO. M., *Captain and Assistant Surgeon.*—Assigned to duty as Post Surgeon, Alcatraz Island, California.—*Par. 3, S. O. 71, Headquarters Department of California*, June 19, 1884.

GIRARD, A. C., *Captain and Assistant Surgeon.*—Granted leave of absence for six months with permission to go beyond sea.—*Par. 11, S. O. 148, A. G. O.*, June 26, 1884.

ORIGINAL LECTURES.

A COURSE OF LECTURES ON DERMATOLOGY.

Delivered at the University of Pennsylvania during the Session of 1883-1884.

BY LOUIS A. DUHRING, M.D.,
PROFESSOR OF DERMATOLOGY IN THE UNIVERSITY.

(Reported by Henry Wile, M.D.)

LECTURE IV.

SYCOSIS NON-PARASITICA; IMPETIGO; ECTHYMA; PSORIASIS; PITYRIASIS; DERMATITIS; PURPURA.

SYCOSIS NON-PARASITICA, sometimes called *sycosis* in contradistinction to *sycosis parasitica* (otherwise and preferably known as *tinea sycosis*), is a chronic, inflammatory, non-contagious disease of the hair-follicles, characterized by papules, pustules or tubercles, perforated by hairs, attended with more or less burning.

The area involved may be small or large, and the affection begins frequently in the form of small lesions, spreading from week to week or month to month until it may cover one or both cheeks. It is rare that the whole face is involved simultaneously. The lesions are, for the most part, discrete, the pustules inclining to be flat and little raised above the surface of the surrounding skin; while, when papular or tubercular lesions are interspersed, they are decidedly raised. The regions attacked are the cheeks, chin, upper lip; either one or all. It seldom runs an acute course, but continues chronic, often for years; even where the patch is small, the difficulty in curing it may be considerable. The burning sensation is sometimes marked. The causes are often obscure.

Its pathology is well understood, and the affection consists first of a peri-follicular inflammation, which soon extends into the hair-follicle, and develops finally into a pustule. The hairs are usually firmly seated, and cannot easily be extracted without giving pain.

In the matter of diagnosis it must be differentiated from tinea sycosis, which, as a rule, is not difficult. In the former the hairs are firmly seated, while in the latter they are readily extracted without pain. If extracted in the former, the root-sheath is also drawn out, and is often in a state of suppuration, while this is not the case in the latter, where the hairs are usually dry and sometimes brittle. Finally, in case of doubt, the microscope will reveal the characteristic fungus of tinea sycosis if this disease be present. It is distinguished from eczema in that the latter disease is not confined to the follicles, but is more diffused. There is besides, in sycosis, little discharge; the lesions do not rupture, but dry up. It occurs at all ages between twenty and sixty years, but is more common in early life.

External treatment is often more valuable than internal. In the majority of cases epilation is unnecessary. Some cases do well under mild treatment, as, for example, a lotion of black wash and oxide of zinc ointment; or sulphur ointment, one or two drachms to the ounce. Other cases call for vigorous applications of soft soap, followed by diachylon ointment. Oleate of mercury, five, ten or fifteen per cent. strength, is also useful. The treatment is similar to that of eczema of the chronic papular or vesicular variety. The hairs should be clipped and kept short. Shaving is useful in some cases, but is hurtful in others.

IMPETIGO.—This disease was formerly confounded with what is now recognized as the pustular variety of eczema. It may be defined as an acute inflammatory disease characterized by pea- or cherry-sized, discrete, rounded and elevated firm pustules, not attended, as a rule, with itching. It occurs in children, commonly about the face and neck, and is at times accompanied by slight malaise. The pustules are of a typical character, are whitish or yellowish, and show no tendency to rupture, but dry up, forming yellowish crusts. It may be distinguished from eczema by the fact that in the latter disease the lesions rupture and are attended with more or less itching; also from ecthyma, in which the lesions are considerably larger, with inflammatory areolæ, and occur for the most part on the lower extremities. From impetigo contagiosa it may be known by the different character of the lesions. The treatment is simple, and consists in the application of any mild stimulating ointment. The disease tends to spontaneous recovery in a short time.

Impetigo herpetiformis is a rare and severe disease occurring in both sexes, but especially in pregnant women. It is often preceded by malaise and even fever. The lesions are itchy and multiform, the disease generally taking on the vesicular or bullous form in this country. The herpetiform grouping of the lesions is characteristic. There are but few cases on record; almost all reported by Hebra were fatal. It must be differentiated from eczema, ecthyma, pemphigus, and impetigo contagiosa.

Impetigo contagiosa may be defined as an acute, inflammatory, contagious disease characterized by superficial vesico-pustules or blebs, with pale or dark yellowish crusts. The lesions are inclined to be flat, soon dry up and crust over. The disease runs its course in one or two weeks, appearing, generally, first upon the face, then upon the extremities, attacking children, and is apt to be mistaken for varicella. It rarely occurs in adults as a primary affection, but may be communicated from children having the disease. The contents of the pustules are auto-inoculable, but the cause of the disease is unknown. It is supposed by some to be due to a fungus, but this is denied by other observers. It is liable to occur in epidemics. Treatment is seldom called for, recovery taking place usually at the end of fourteen days or sooner. It must be distinguished from pustular eczema, impetigo, varicella, pemphigus, and herpes iris.

Ecthyma is a common disease among the poor and neglected. It is an inflammatory affection characterized by large, flat pustules, which soon dry up and form brownish crusts. It occurs generally on the lower extremities, and yields to simple treatment, such as the application of a mild calomel or ammoniated mercury ointment, twenty grains to the ounce. It may be distinguished from syphilis by the absence of ulceration and loss of tissue.

Psoriasis is one of the most important of the diseases of the skin. It may be defined as a chronic disease characterized by reddish, dry, inflammatory, more or less thickened patches, variable as to size, shape and number, and covered usually with abundant whitish or grayish, mother-of-pearl-colored, imbricated scales. The disease varies greatly as to the extent of its development, but as a rule its characteristics are well marked. It begins in small reddish spots, which soon become scaly. These increase in size slowly, or sometimes rapidly, and, as a rule, are sharply circumscribed. The degree of inflammation varies. Itching or burning, though not infrequently absent, may be annoying symptoms.

The different sizes and shapes of the lesions give rise to the several varieties of the disease; thus, lesions in the form of points, punctata; drops, guttata; coin shaped and sized, nummularis; circles tending to clear in the centre, circinata; and segments of circles, giving a serpiginous appearance, gyrata. Where there are large extensive patches without any special form, diffusa; where large parts of the surface, as the trunk or extremities or both, are chronically involved, inveterata. All regions of the surface may be attacked, but more specially the extensor surfaces and the elbows, knees, back, scalp, and forehead. The palms, soles, and nails may also be invaded. The face is usually exempt. It is non-contagious, and as a rule is found in strong, plethoric, and otherwise healthy subjects rather than in the debilitated. The disposition to its development is sometimes inherited. It never attacks infants, and only rarely appears before the age of eight, and, as a rule, not before fifteen or twenty. It occurs in both sexes nearly equally, and is more common in northern climates. In ten thousand cases of diseases of the skin collected by McCall Anderson, of Glasgow, seven hundred and twenty-five were of psoriasis. It may also be associated with a gouty or rheumatic state.

Pathologically, the disease consists of hyperæmia with hyperplasia of the epidermis, with secondary inflammatory changes in the corium, resulting from pressure. It must be distinguished from eczema, syphilis, tinea circinata, and lupus erythematosus. The sharply defined outline of the lesions, and the presence of the characteristic pearly scales, are usually sufficient to establish the diagnosis.

As to treatment, the constitution and the general condition of the patient must be taken into consideration; also the question as to how much time the patient can devote to the disease, and whether the patient is a child or an adult. Arsenic is our most valuable remedy, and it should be used judiciously and for a long period. Fowler's solution, given in two or three minim doses to an adult for months, will cure many cases. There are, however, examples in which arsenic will aggravate the disease. In these cases sometimes phosphorus, phosphide of zinc, carbolic acid, and tar capsules will prove useful. Also alkalies, as liquor potassæ, ten to twenty drops three times daily, freely diluted. This latter remedy is most useful in many cases.

Local treatment is also of great value. Applications of sapo mollis, or of an alcoholic solution of soap, followed by baths, will often be found useful. Alkaline baths must also be mentioned as serviceable adjuvants in the treatment. In highly inflammatory cases, inunctions with olive oil will sometimes prove efficacious. The most generally useful remedy is tar, in one form or another. Tar ointment is one of our most reliable remedies. Oil of cade, pure or with alcohol, one to three drachms to the ounce, applied with a brush; liquor carbonis detergens; liquor picis alkalinus; oleate of mercury; ointment of the nitrate of mercury; white precipitate ointment; and pyrogallic acid, are all excellent remedies. Chrysarobin is very valuable. It should always be used with caution. It is liable to set up dermatitis of the surrounding skin. It stains a purplish or mahogany color everything with which it comes in contact, and this is its disadvantage. Still, it generally has a very happy effect on the lesions, often curing them rapidly. It is best applied in the following form:

R.—Chrysarobini, ... ʒj.
Liq. guttæ perchæ, ... f3x.—M.

Sig.—To be painted on the lesions after the scales are removed. By this means it is held to the lesions, and is less liable to stain. It may also be applied as an ointment, in the strength of from fifteen grains to one drachm to the ounce.

Pityriasis rubra is a rare disease, having much resemblance both to psoriasis and to squamous eczema. It is an inflammatory disease involving usually the entire surface of the body, and is characterized by deep-red coloration and abundant and continuous exfoliation of the epidermis in the form of large, thin, whitish scales. The disease lasts for months or years, often relapsing from time to time. The uniform red coloration, together with the rapid and abundant exfoliation in the form of extremely thin flakes, with curled-up edges, is characteristic. Treatment in most cases has little effect upon the course of the disease. Internally, arsenic is indicated, and locally mild, non-stimulating ointments may be employed.

Pityriasis rosea is a rather rare disease which has recently received attention from observers. It is inflammatory, occurring chiefly on the trunk, and is characterized by discrete or confluent macules, or, rarely, maculo-papules, varying in size from a pea to a silver quarter- or half-dollar. The lesions are furthermore rounded or ovoid; of a rosy, pale-red or red color; later becoming yellowish or brownish, pigmented and scaly, accompanied by but little thickening of the skin. The scaling is usually furfuraceous. It is non-contagious, non-parasitic; may run an acute course in a few weeks, or, what is much more common, last for months. It is, as a rule, unaccompanied by itching or other subjective symptoms. The disease was not recognized in this country until a few years ago, when Dr. Duhring called attention to its distinctive features. From psoriasis and syphilis it is distinguished by the absence of infiltration, and from tinea versicolor by the absence of fungus. Some French writers claim that it is a parasitic disease, but in none of Dr. Duhring's

cases was a fungus found. It runs a benign course, and tends to spontaneous involution. It does not seem to be influenced much by treatment.

DERMATITIS signifies a simple inflammation of the skin without reference to cause, due to such external agencies as heat, cold, cutaneous irritants, caustics, etc. The lesions vary with the cause, the extent of exposure, etc., and may be circumscribed or diffused. The clinical signs of inflammation are heat, swelling, pain, or itching or burning, which are present in varying degrees of intensity.

Dermatitis exfoliativa is a rare affection, and has been described under numerous titles, such as "general exfoliative dermatitis," "recurring exfoliative dermatitis," "desquamative scarlatiniform erythema," "recurrent acute eczema," "acute general dermatitis," and "recurrent exfoliative erythema." There is a great diversity of opinion as to the true nature of the disease. It must be distinguished from eczema, psoriasis, pityriasis rubra, and pemphigus foliaceus. The disease is accompanied with more or less febrile disturbance, and is characterized by localized or generalized acute erythematous, more rarely vesicular or bullous, inflammation, followed by a variable degree of desquamation or exfoliation of epidermis. There is also a tendency to relapse.

Dermatitis traumatica is produced by direct violence, contusions, irritating articles applied to the skin, and excoriations due to the presence of parasites, the latter being generally accompanied by pigmentation.

Dermatitis venenata is a characteristic inflammatory condition caused by contact with poisonous substances. Among the most common causes are the Rhus plants commonly known as poisonous sumach, or dogwood, and poison ivy, or oak. This eruption occurs for the most part about the hands, forearms, face, lower extremities below the knees, and genitalia, and consists of a diffuse erythema, with more or less œdema, accompanied by the appearance of vesicles, blebs, and pustules. Other causes are nettle, arnica, mezerion, goa-powder, mustard, cantharides, hartshorn, croton oil, etc. The eruptions all run an acute course, and vary in intensity in proportion to the susceptibility of the individual. Some persons may handle the poisonous plants with impunity; others again, on the slightest contact, become affected with the eruption. Some authorities contend that the affection is an eczema, but the lesions are different, being multiform, angular, and having a tendency to remain intact, while those of eczema are rounded, soon rupture, and become covered with exudation and crusting. The treatment is simple and satisfactory, external applications alone sufficing. A lotion of black wash, followed by oxide of zinc ointment, or the fluid extract of grindelia robusta, one drachm to two or four ounces of water, are valuable. The lotions are to be dabbed on every two or three hours. Lotions of the hyposulphite of sodium, one drachm to the ounce of water, or sulphate of zinc, two to five grains to the ounce, are also useful.

Not infrequently violent dermatitis is produced by aniline and coralline dyes of undergarments and stockings. Inflammations may also be provoked by individuals upon themselves, with a view to excite sympathy, with nitric acid, which gives rise to a bullous eruption; also with hartshorn and other substances. These are entirely artificial, and are known as "factitions" or "feigned" diseases of the skin.

Dermatitis calorica is an inflammation caused by extreme degrees of heat, and of cold, as in frost-bite.

Dermatitis gangrænosa is an obscure disease of the skin, occurring in the form of circumscribed or diffused patches of gangrenous skin, which, after a variable course, separate as a slough. It is usually accompanied by febrile symptoms, and may terminate fatally.

Dermatitis medicamentosa. Under this head are classed certain kinds of eruptions which may follow the ingestion of a number of remedies in common use. Thus quinine, belladonna, chloral, salicylic acid, and mercury may give rise to an erythematous efflorescence; bromide and iodide of potassium, as a rule, give rise to pustular eruptions, resembling acne, except as to distribution. The lesions are scattered over the body, and are situated around the sebaceous glands, from which the bases of the remedy are eliminated. Copaiba, also, sometimes causes a cherry-red or violaceous erythematous or papular eruption.

HÆMORRHAGIÆ, in mild or extensive form, are met with, from time to time, in the corium. They occur through diapedesis or as an extravasation, and are divided into two classes: idiopathic, or those resulting from external injury, as from wounds, contusions, bites of insects, as the flea, pediculus, etc., and symptomatic, or those which occur as a manifestation of internal disease, *e. g.*, purpura. The characteristic of the lesions of purpura, as distinguished from inflammatory lesions, is that the former do not disappear under pressure.

PURPURA may be defined as consisting of variously sized and shaped, non-elevated, smooth, reddish, hemorrhagic patches, persisting under pressure. There are three varieties:

Purpura simplex consists of small, pin-head-sized lesions, usually occurring on the lower extremities, especially upon the flexor surfaces of the thighs. They make their appearance suddenly, and are accompanied by little or no constitutional disturbance. On disappearing, they leave pigment residue of a yellowish, greenish, brownish color.

Purpura rheumatica is preceded by malaise and rheumatic pains in the joints, especially those of the lower extremities. The eruption makes its appearance suddenly or gradually, and consists of pale-red or reddish spots, varying in size from a split pea to a finger-nail, and are, as a rule, more marked about the arms and legs. It persists a few weeks or months, new lesions appearing from time to time, and as it fades away, the lesions change color, assuming a yellowish, greenish or brownish hue. It must be distinguished from papular syphilis.

Purpura hæmorrhagica, also called land scurvy, is often preceded by constitutional symptoms of a marked character, such as weakness, loss of appetite, headache, and general malaise. The eruption usually appears first upon the extremities, and soon extends upon the trunk, and consists of variously sized, irregular, hemorrhagic spots. Simultaneous with the eruption upon the surface, hemorrhages may occur in other parts, as in the mouth, bowels, etc. The disease may last for days or weeks; it may relapse, and may end fatally. It occurs in children and adults, and is not attributed to

bad hygiene or want of vegetable diet, occurring in the strong as well as in the weak.

Among remedies, electricity may be mentioned, which in some cases has proved useful. Ergot, iron, and quinine are all valuable agents. Attention must also be given to diet, which should be as nutritious as possible. Rest should be enjoined, and a horizontal position be maintained.

TRACHEOTOMY IN CROUP.[1]

BY GEORGE W. GAY, M.D.,
SURGEON TO THE BOSTON CITY HOSPITAL, BOSTON, MASS.

THE mortality in croup is so great, and the results of all kinds of treatment are often so unsatisfactory, that many members of the profession entertain the opinion, that all their efforts are powerless to save life, or to give even temporary relief. This statement applies especially to the operation of tracheotomy. Always an anxious, and oftentimes a difficult one to perform, requiring the most intelligent, skilful, and unremitting care in the after-treatment, yet it has given more relief, and saved more lives in pseudo-membranous laryngitis than all other remedial measures. Not infrequently the operator will meet with accidents, and occasionally may lose a patient upon the table, yet he may rest assured that, in the long run, he will do more good than harm, and that he will save some lives which would probably have been lost had he not interfered.

It will be the object of this paper to show from the records of the Boston City Hospital for the past twenty years, and from other sources, that the results of this operation are not as unsatisfactory as has been supposed; that surgical treatment offers a better prospect of success, than any other; that a fair proportion of the patients can be saved; and that many more can be greatly relieved by a timely resort to this measure.

The term croup is used here in its generic sense, as meaning an acute laryngeal obstruction to respiration, due to the presence of a false membrane.

Two varieties come to the notice of the surgeon: the membranous and the diphtheritic. The false croup so common in young children can usually be recognized from the fact that it occurs suddenly, and in the night, is paroxysmal, of short duration, less severe in character, yields readily to treatment, and seldom, if ever, terminates fatally. Acute catarrhal laryngitis of adults is not a common affection. The symptoms resemble those of the membranous disease, and may require surgical interference.

As a correct diagnosis of the two kinds of laryngitis under consideration is thought by many to be of great importance in regard to the prognosis and treatment, I may be pardoned a few words upon the subject.

The profession has always been, and still is, divided upon the question of the identity of membranous and diphtheritic croup; one portion claiming that the former is purely a local, and the latter a constitutional disease; while the other portion, with equal tenacity, assert that they are essentially one and the same affection, under different manifestations.

The writer takes the ground that membranous croup is a distinct and separate disease from diphtheria, for the following reasons: It is not contagious; it is a local lesion confined to the air-passages; it causes death by mechanical means; it never results in systemic infection; it has never disappeared from notice for long periods of time, and over a large extent of territory, as has diphtheria.

Much of the confusion that exists upon this question is due to the fact that authorities are not agreed as to what group of symptoms shall constitute either malady. Dyspnœa is the prominent and important symptom common to both. Glandular enlargements, nasal discharges, albuminuria, and paralysis are the distinguishing features of diphtheria, and cases presenting any of these characteristics should not be called membranous croup.

The older members of the profession, who have had opportunities of studying croup at a period when diphtheria was unknown in this country, and whose opinions are entitled to the greatest respect, recognize the marked clinical distinctions between the two affections. The writers of that time generally deny the existence of contagion, and say nothing about glandular complications, or other symptoms of blood-poisoning. The croup of these days was a purely suffocative affection, and it is not reasonable to suppose that a disease of so grave a character as diphtheria should have shown itself in this country for seventy-five years as simply a local, non-contagious laryngitis, and not have presented its most prominent feature, namely, septicæmia.

It is stated by some authorities that an exudation upon the fauces necessarily indicates diphtheria; and that the cervical glands are not implicated while the membrane is confined to the larynx, because of the peculiar distribution of the lymphatics. Dr. John Ware, who wrote a most admirable monograph on croup in 1842, long before diphtheria had made its reappearance in America, reports the presence of an exudation in the pharynx in seventy-four out of seventy-five cases examined with reference to that point. He says nothing of enlarged glands, nasal discharge, or other septic symptoms, as so keen and reliable an observer would certainly have done, had they existed. It is not consistent with the history of diphtheria, that it should have occurred so many times in the practice of Dr. Ware and his contemporaries, without presenting some of its constitutional symptoms.

Fatal cases of diphtheria in which the larynx is not affected are common. Idiopathic croup, on the contrary, is invariably a laryngeal disease, is confined to the air-passages, and causes death by suffocation. In short, membranous croup is simply that, and nothing else; while diphtheria, though occasionally attended with croup, is always something more.

Although I am aware of the fact that a majority of the cases of croup of late years are diphtheritic, and that in exceptional cases it may be difficult to make a differential diagnosis, yet I submit the fol-

[1] Read before the American Surgical Association, May 2, 1884.

lowing statements as the result of my experience and study of the subject:

First. There is an acute, non-contagious disease of the larynx, characterized by the presence of false membrane, which causes the principal symptom, dyspnœa; and often destroys life. This is membranous, or idiopathic croup, and is of rare occurrence.

Second. There is an acute, contagious affection presenting a similar exudation in the larynx and other localities, accompanied by symptoms of blood-poisoning, such as enlarged glands, nasal discharge, albuminuria, debility, and coma. This is diphtheritic or secondary croup. For twenty years it has been the prevailing type in the United States, and it is very fatal.

Third. There are occasionally fatal cases of acute laryngeal stenosis, in which no membrane is seen during life or at the autopsy. As thickening and œdema of the mucous membrane are present in these cases, they are probably of the same nature, and require the same treatment, as the membranous form.

But while a doubt may exist in the minds of many as to the character of these affections, there can be none as to the duty of the practitioner. It is for him to study the condition of the patient, rather than the name of his malady. The treatment should be based upon the symptoms presented, and not upon a disputed theory of the nature of his disease.

Surgical interference is often necessary to relieve the difficulty in breathing, and, in the opinion of the writer, the cases of probable membranous laryngitis, attended with severe and increasing dyspnœa of over twenty-four hours' duration, are rare, in which the patient, whatever may be his general condition, should be refused the benefit that may result from opening the trachea. It is of the first importance that the mechanical obstruction to respiration should be removed at the earliest moment possible.

Before resorting to any operative measures, it is always well to form some idea of the probable result of the case, if it be allowed to proceed without them. The evidence which I have been able to gather touching the results of the medical treatment of croup, is somewhat conflicting, as will be seen by the following remarks:

Meigs and Pepper report fifteen spontaneous recoveries in thirty-five cases of pseudo-membranous laryngitis, mostly of the diphtheritic variety. Dr. J. Lewis Smith, in twenty-one cases of diphtheritic croup, has had seven successful results without an operation. In speaking of idiopathic croup, Dr. Agnew says: "I am of opinion that, with American practitioners, the recoveries without operation are at least fifty per cent." Dr. Ware's statistics show that thirty cases out of thirty-three, treated by the expectant method, terminated fatally. He did not make use of the depressing treatment, which was in vogue at that time, but relied upon opium, calomel, and steam.

Dr. Cheever, Professor of Surgery at Harvard University, writes as follows: "After reflection, I cannot recall a case of membranous laryngitis that I have known to recover without tracheotomy."

As the result of written inquiries of about thirty prominent practitioners in New England, I have heard of the recovery of between thirty and forty cases under medical treatment, which is a small proportion of cases observed. One physician reports seven cases; another four, another three; several had never seen a case of spontaneous recovery, and they all agree that such results are rare. These gentlemen have been in practice for a period of from thirty to sixty years.

Upwards of four hundred cases of diphtheria have been admitted to the Boston City Hospital during the past eight years. Forty of these patients, suffering from undoubted diphtheritic croup, as indicated by the presence of membrane, glandular enlargements, dyspnœa, and cyanosis, received medical treatment only, and every one died. *Not a single case of pseudo-membranous laryngitis has ever recovered in this hospital without an operation.* In the light of such evidence, I can but conclude that the expectant plan of treating croup is far from satisfactory. On the other hand, the results of the operative treatment are much more encouraging.

The formidable array of statistics given to the profession through the arduous labors of Cohen, Mastin, and others, comprising over eleven thousand operations as collated by Dr. Agnew, prove that from one-quarter to one-third of the cases of tracheotomized croup recover. Cohen reports one hundred and ten successful results out of one hundred and sixty-six cases, mostly in private practice. Drs. Jacobi, Voss, Krackowizer, and von Roth saved fifty out of two hundred and thirteen. Of seventy-nine operations performed by surgeons in Philadelphia, nineteen were successful. Dr. John H. Ripley, of New York, has had thirty favorable results, in one hundred operations. The writer has performed tracheotomy sixty-two times for croup, with twenty recoveries. Twenty-one of these operations were performed in 1883, of which ten were successful. Fifteen cases were in private practice; only one recovered.

Tracheotomy for this disease has been performed one hundred and eighteen times at the Boston City Hospital during the past twenty years. Thirty-nine, or one in three, were successful. That the cases were not selected, is conclusively shown by the fact that three patients died during the operation from shock and exhaustion, not from hemorrhage; thirty-four died within twenty-four hours; and fifty-six, or more than one-half of the fatal cases, within forty-eight hours. Four, if not five, of the successful cases were practically moribund at the time of the operation.

While the records are not sufficiently complete to enable me to give the exact number belonging to each class, yet the diphtheritic variety largely predominated.

The ages of these patients ranged from nine months to forty-one years. The youngest to recover was eleven months; the oldest, sixteen years. Four aged two years, and five aged three years got well.

Membrane was visible in the fauces or trachea in a large proportion of both the successful and unsuccessful cases. Its absence was noted in only three of each class. It need not be said, that in every instance there was present severe, constant, and

increasing dyspnœa, exhausting the strength and threatening suffocation.

As a rule, the operation was followed by marked temporary relief; and in many of the fatal cases the difficulty in respiration did not return until the patient was comatose from blood-poisoning, and hence beyond suffering. In a few instances the smaller air-tubes were so extensively invaded by the deposit that no benefit resulted from the procedure.

A large majority of the patients had received appropriate medical treatment previous to entering the hospital, and were only sent there when it had become evident that an operation was the only alternative. It follows, of course, that many of the cases were in a most deplorable condition. It is the rule with us, however, to open the trachea at once, if there is the least prospect that the patient will survive it, and in more than one instance the result has justified the practice. For example, a child came under my care last winter, suffering from malignant diphtheritic croup. There were present faucial exudations, glandular enlargements, foul nasal discharge, dyspnœa, cyanosis, and impending coma. There did not seem to be the slightest chance for success, yet, after some hesitation, the operation was performed. Immediate and entire relief followed, and the child recovered. So many of these desperate cases have been saved at the last moment by different operators, even resuscitation having been followed by success, that a resort to this measure is advisable under almost any circumstances.

In view of the natural antipathy entertained by the public against a surgical operation, it is fair to conclude that few, if any, patients are subjected to this one, until a reasonable trial of other measures has been made; and hence it must be the rare exception that a tracheotomized patient would have recovered without it.

Again, taking into consideration the fatal character of the affection, the unsatisfactory results of the expectant treatment, and the impossibility of determining the cases which would recover spontaneously a resort to this measure is justifiable in urgent cases even if the diagnosis is doubtful. Waiting for a clear diagnosis is, in some instances, simply waiting for an autopsy.

The advantages of an early tracheotomy are, that the patient is better able to undergo it; the strength is preserved, more nourishment can be taken, and more sleep secured; time is gained, in which it may be hoped that the disease will run its course; and finally, it seems reasonable to suppose, as is claimed by some writers, that it tends to prevent those pulmonary complications so common in the later stages of the disease. Other things being equal, early operations will probably give better results than late ones.

Little need be said here as to the best method of performing tracheotomy. Every operator of much experience gradually acquires one of his own. I learned long ago to be chary of the use of ether in these cases, as it may impede or suspend the respiration, and it often increases the shock and prostration. The pain is not very severe, and usually ceases as soon as the skin is divided. With good assistants, the operation can be safely performed in a majority of instances without an anæsthetic.

Having performed the high and low operation many times, I have come to prefer the former because the trachea is more easily reached, there is less danger of hemorrhage, and it is more easily controlled, there is less liability to abscess and emphysema, and because nothing is gained by opening the trachea an inch or so lower, as the obstruction, if present, is at or below the bifurcation. I do not hesitate to divide the cricoid cartilage, or the isthmus of the thyroid gland, and have never seen any harm result from so doing. The trachea is secured with a tenaculum before being incised, thus avoiding the danger of missing it, or of losing sight of the opening, mishaps which are embarrassing, and not uncommon. A moderate sized silver tube with a movable shoulder is always used. This has been worn in the above cases for periods varying from five days to two or three years. None of the patients have been compelled to wear it permanently.

I have found the most satisfactory method of getting rid of the tube to be as follows:

About a week after the operation, if the respiration is free and easy, the canula is quietly removed, and the patient is left undisturbed. No trials are made to ascertain if he can breathe through the larynx. As the wound in the trachea contracts, respiration by the natural channel is gradually reëstablished.

I have never seen a patient die from hemorrhage during this operation, either before or after the trachea had been opened, and I do not think it has ever occurred at the City Hospital. Should respiration become impeded by the presence of blood in the bronchi, we are directed by some authorities to apply our mouth to the wound, and suck it out, or to do so by means of a catheter, or other tube.

Nature gets rid of offending substances in the air-passages, by means of forcible expirations, or cough, and we should try to imitate her. The writer has been called upon to clear the bronchial tubes of blood under the following circumstances: A young man was brought to the hospital, who had shot himself in the mouth, the ball lodging in the back of the neck to the left of the spinous processes. The patient having been etherized, an incision was made, and the bullet was readily extracted. At that moment, however, his face became livid, and he ceased to breathe. The trachea was immediately opened, a large catheter introduced, and air was forcibly blown into the lungs, with the result of driving out a large quantity of blood.[1] Respiration was soon reëstablished, and consciousness returned. The ease and rapidity with which the blood was ejected from the bronchial tubes was as surprising as it was satisfactory.

It is a physical impossibility to suck anything out of the trachea, unless air has a free ingress to supply the vacuum. Forcible distention of the lungs through a tube is attended by a return current of air, the velocity of which is in direct ratio to the power exerted. This effect is much more readily obtained by strongly inflating the lungs, than by suction.

[1] The source of the hemorrhage was from a wound in the vertebral artery; it did not recur, but the patient died of pleurisy in a week.

Furthermore, in cases of croup, whether contagious or not, no one is called upon to risk his life in trying to suck out the contents of the bronchial tubes. Too many valuable lives have been sacrificed in that way, and in view of the fact that there are other and better methods of accomplishing the object, the plan should be totally abandoned. Forcing air into the lungs from the mouth of the operator is rapid, efficacious, and comparatively safe; trying to empty the bronchial tubes by suction is always dangerous, and rarely successful.

Next to nourishment, I consider steam to be the most important factor in the treatment of these cases. So essential is this agent in my opinion, that I have repeatedly refused to operate in private practice, when it was impossible to obtain a sufficient supply. At the hospital the pipes are tapped, and the steam is conducted through a rubber tube, attached to a frame on castors, and directed upon the throat of the patient. The severe cases are made to inhale it constantly, with the result of softening the secretion, quieting the cough, and often relieving the dyspnœa.

Neither medicated nor atomized fluids have been used of late for inhalation. The effects obtained from the use of warm steam seem to be as beneficial as they were when lime-water, carbolic acid, etc., were in vogue.

It is desirable that two efficient nurses should be in attendance, one to relieve the other, who have had special training, and who are able to remove and replace the outer canula, and clear out the trachea in an emergency. It is not safe to leave these patients in charge of inexperienced friends, while the overtasked nurse is getting her sleep. In short, the service of the sick-room should be quiet, regular, intelligent, and untiring.

In conclusion, I would briefly mention the following reasons for resorting to tracheotomy in membranous laryngitis.

The disease is always dangerous, and very often fatal.

The results obtained from medical treatment alone are extremely unsatisfactory.

Tracheotomy gives more relief, and saves more lives, than any other method of treatment known to the profession.

It seldom hastens death, and still more seldom causes it.

Finally, it affords the friends the great and lasting satisfaction of knowing that everything possible has been done for the patient.

ETHERIZATION BY THE RECTUM.

BY BERNARD PERSH, M. D.,
HOSPITAL STEWARD, U. S. A.

THE observations of Dr. Daniel Mollière, surgeon of the Hôtel Dieu, at Lyons, on the method of administering ether by the rectum, published in the *Lyon Médical*, of March 30, 1884, have attracted considerable attention on this side of the Atlantic, and this novel way of producing anæsthesia has been tried in several of our large cities during the past few weeks. Much was expected of the new method, and it was believed by some that it would form a new era in the administration of ether, but the cases in which it has been tried, and the results of which have been published, do not warrant such conclusions at the present time.

In looking over thirty cases in which ether had been given by the rectal method it was found—

Largest quantity of ether given, six ounces; smallest quantity, one and one-half ounces; average, 2.91 ounces.

Minimum time consumed in producing anæsthesia, three minutes (child eight months old); maximum time, thirty-two minutes; average, thirteen minutes.

In twenty cases anæsthesia was produced and maintained by the rectal method only.

In ten cases the inhaler was used in addition to the rectal tube.

Diarrhœa was observed in ten cases, the number of passages varying from three to fourteen; five of these cases had bloody stools, one proved fatal. No diarrhœa in twenty cases.

Stage of excitement absent in sixteen cases; mild, short, or light in seven cases; moderate in five, violent in two.

Vomiting took place once during or after operation in fourteen cases; no vomiting in sixteen cases.

The advantages of the new method appear to be that it reduces the state of excitement, makes vomiting during and after administration much less liable, requires less ether, and offers ready means to estimate the amount given. To patients who have taken ether on previous occasions, the rectal method appears to be more acceptable, since the disagreeable odor of the ether, as well as the feeling of suffocation, is entirely absent. Its adaptation to operations on the neck, face, and head appears to be very prominent.

The objections to the method are that the time necessary to produce anæsthesia is greatly prolonged; that diarrhœa and irritation of the rectum seem to be quite common; and that in some cases inhalation is necessary to produce the desired result. In three cases the effects of the ether were greatly prolonged, and insensibility continued from twenty to thirty minutes after removal of the rectal tube. In one case an hour elapsed before consciousness gradually returned by the use of stimulants hypodermatically and the hot air bath. There seems to be no ready means to relieve the prolonged anæsthesia in such cases. While by the old method the anæsthetic agent can be quickly withdrawn by the removal of the inhaler, or towel, it appears almost impossible to expel the unabsorbed ether vapor from the intestines.

The apparatus employed in the majority of cases consisted of a graduated vessel, or bottle, with perforated cork containing two short glass tubes, one a funnel-tube supplied with stopper, and the other connected by about two feet of rubber tubing with a vaginal nozzle of a Davidson's syringe, or a rectal tube. The bottle contained the ether and was immersed in a pitcher filled with water, so hot as to be uncomfortable to the hands, or of a temperature varying from 110° to 140°. In repeating the experiments with an apparatus similar to the above, it became at once evident that something was re-

quired to complete the arrangement, and to indicate whether the process of evaporation was progressing favorably, or whether there was any resistance or obstruction in the tube, or at its outlet. A long U-shaped funnel-tube, the trap of which was filled with ether, and the long end of which reached to the bottom of the vial, was, therefore, substituted for the short tube with the desired result. Any condensation of ether within the conducting pipe, or nozzle, or any other obstruction preventing a free escape of the vapor, as well as too rapid evaporation, being at once indicated by the movement of the ether in the funnel-tube. In renewing the water in the pitcher by simply pouring out some of its contents, and substituting hot water from the top, the apparatus was not only disturbed, but the evaporations of ether became for a short time very rapid, and unequal, owing to the hot water coming directly in contact with the bottle. To this cause may possibly be ascribed the fatal result following anæsthesia by the rectal method in a child eight months old. To amend this defect, a teapot, made of delf-ware, and holding two quarts, was substituted for the pitcher. The colder water was drawn off by a siphon from the bottom of the vessel, and hot water added through the spout, thus favoring gradual rise of temperature. An apparatus of this kind could be made of tin, or any other metal, but it should be constructed on the same principle as a water-cooler, in order to retain heat as much as possible, which is a very important point.

In using this arrangement it was found that at a temperature of 150° two ounces of ether were evaporated in eleven minutes, at 140° in sixteen minutes, at 130° in twenty minutes, at 120° in twenty-four minutes, and these results were only to be obtained by keeping up a steady temperature. The flow of the vapor at temperatures varying from 125° to 140° was steady, and it could be seen to issue, or fall with some force from the opening of the vaginal tube, which formed the end of the conducting pipe. Rubber bags were distended rapidly and equally by the vapor, and the completion of the distention was readily indicated by an upward movement of the ether in the funnel-tube. By allowing the temperature to fall below 115° the distention of the bags was considerably slower, and the vapor lost its power of expansion almost entirely when generated by a temperature of 105°. Of course, the ether continued to boil until the temperature of the water fell below 98°, but most of the vapor produced at a low temperature was condensed before it reached the bags. The bags were kept in warm water at a temperature of 99° to 100°. However well managed, condensation of ether vapor will take place, and this cannot be prevented, excepting the tubes are kept at a temperature above the boiling-point of ether, say 100°. If condensed ether is forced into the rectum, it must produce a burning sensation, and may possibly be the cause of irritation. To prevent this as much as possible, the tube might be removed from time to time, and emptied, or, what is better, the condensed ether might be allowed to escape from a tube, closed by a stopcock, and inserted into the side of the rectal tube, just below where it projects from the rectum. That end of the tube of a self-injecting syringe which serves for the attachment of the nozzles, is usually made with two openings, and answers the purpose admirably.

An earthen vessel of a conical shape, and holding two quarts of water of 130°, will lose about 5° every ten minutes, and it will, therefore, be necessary to add hot water every five minutes, if a nearly steady temperature is to be maintained.

It seems that the method of giving ether by the rectum must be carefully watched, and the thermometer should be frequently consulted. In looking over the cases which have been reported, it is found that in one case, in which the administration was followed by five bloody stools, four ounces were given in twenty minutes, at a temperature varying from 140° to 120°. Experiments prove that a steady temperature of 152° is required to evaporate four ounces of ether in that space of time. In three other cases in which the hand was used to indicate the temperature, anæsthesia was maintained for half an hour after discontinuing the ether, and two of the cases were followed by diarrhœa. The safest temperature is probably between 130° and 120°, and the gauge as well as the distention of the rubber bags indicated that the vaporization of the ether and its expansive power are very steady and gradual at these temperatures. By commencing with the higher temperature, and allowing the process to proceed without the addition of hot water, it was found that two ounces of ether could be evaporated in twenty minutes, and this quantity seems to be more than sufficient to produce complete anæsthesia by the rectal method.

These remarks may appear to be too specific in some instances, but it is believed that the experiments above described will be of practical value in further trials of the new method, and it should be remembered that success in most cases is only to be obtained by paying careful and close attention to details.

THE FRANKFORD ARSENAL, PA.,
May 20, 1884.

MEDICAL PROGRESS.

INJECTIONS OF CITRATE OF IRON IN CHLOROANÆMIA.—*El Siglo Medico* recently published the description of an interesting case of chloroanæmia cured by hypodermatic injections of citrate of iron. The patient had presented symptoms of chloroanæmia since 1879, and had become excessively reduced in weight. It was determined to give dilute hydrochloric acid in gtt. viij doses, and, at the same time, hypodermatic injections of citrate of iron in the proportion of gr. xxx to f℥v of water; ♏xv to be injected in different parts of the body every day. After forty injections the morbid phenomena disappeared, and the patient had gained over twenty pounds.—*O Correio Medico de Lisboa*, March 15, 1884.

DIVULSION OF THE PYLORUS.—On June 9th, this operation was performed, for the first time in Venice, by DR. S. C. BASILIO FRATTINI. Thus far the patient has done well.—*Gazz. degli Ospitali*, June 18, 1884.

THE TREATMENT OF ASIATIC CHOLERA BY INHALATIONS OF OXYGEN.—Reports from Toulon state that resort is being made to inhalations of oxygen in the treatment of cholera now epidemic in that city. In connection with this matter, it may be interesting to cite the following from *A Treatise on Inhalation*, etc., by Dr. J. Solis-Cohen, of this city, first edition, Phila., 1867, pp. 194, 195:

"In the 'Reports on Asiatic Cholera in the Madras Army, from 1828 to 1844,' by Samuel Rodgers, London, 1848, the inhalation of oxygen is spoken of favorably.

"Dr. Wittemeyer, of Nordhäusen (*Deutsche Klinik*, Oct. 13, 1866, p. 306), has suggested the inhalation of oxygen and of the vapor of water, in the stage of asphyxia in cholera. He is led to the employment of these inhalations because the functional activity and absorbent powers of the alimentary canal being impaired, there remains open to us but the respiratory tract by which to convey remedies to the system at large. He considers two indications highly important in this stage of cholera, the first being to convey water to the thickened blood, for which purpose he proposes that the patient shall inhale steam and hot water nebulized from one of Siegle's apparatus, the temperature of the nebulized water being kept sufficiently warm by a flame under the medicine-glass; then, he contends, that as the thickening of the blood impedes the interchange of gases in the lungs, the second indication is to convey oxygen to the blood, which is best accomplished by inhalation of the pure gas. This, he maintains, would have a more promptly excitant action upon the heart than any ordinary medicine that could be administered in another way, and, as a result, the blood would be enabled to circulate through the vessels more rapidly, and become better and better prepared to imbibe the desired amount of vapor of water and of oxygen.

"Dr. Jütte, of Stettin (*Deutsche Klinik*, Dec. 1, 1866, p. 436), commenting on the article of Dr. Wittemeyer, says that he had made the experiment of administering oxygen by inhalation to four adult patients, during the short and severe epidemic which prevailed in and about Stettin in the year 1856, and that the administration had been conducted with great care and sufficient frequency, but that all of his patients died without evincing the least sign of even temporary improvement, and he was so disappointed with the result that he did not pursue the experiment any further."

According to the latest cablegrams from Toulon, the oxygen inhalation treatment has proved unsatisfactory.

THE SUBCUTANEOUS INJECTION OF IRON.—Of all the organic and inorganic salts of iron with which experiments were made, GLÆVECKE found that the citrate of iron is most easily and certainly absorbed. Sulphate of iron is made easy of absorption by the addition of two or three times its weight of citrate of sodium, whilst peptonized iron is very badly absorbed, and ammoniated sulphate of iron not at all. The iron is chiefly excreted by the kidneys, and in small quantities by the liver. It begins to appear in the urine within about one-half an hour after the injection, reaches its maximum in from two to four hours, and disappears in about twenty-five hours. In the urine, iron always appears in the ferrous condition, in whatever form it may have been injected. Bile contains iron in the ferric form. Blood-serum and peritoneal fluid contain it, after injection, both in the ferric and ferrous forms. The aqueous humor contained but little, from which Glævecke concludes that the iron exists in the body as an oxide, and in the form of an albuminate, and only becomes reduced to the ferrous state in the urine.

Glævecke used citrate of iron with good results in ten cases. For adults, the dose for injection is gr. jss, in a ten per cent. solution; for children, the dose is gr. ¾. The solution must be clear, and not over one month old. Large doses cause symptoms of poisoning, general discomfort, and vomiting in about thirty minutes. This treatment was used in two cases of nephritis, with the view of reducing the excretion of albumen, but did no good.—*Centralbl. für die med. Wissensch.*, May 24, 1884.

A CASE OF TÆNIA FLAVO-PUNCTATA.—DR. E. PARONA recently presented to the Academy of Medicine in Turin, a very interesting case of Tænia flavo-punctata. The patient was a child two years of age, and an examination of its feces showed ova which somewhat resembled those of the Tænia solium. A dose of castor oil was given in order to clean out the bowels; the patient was then put upon a milk diet, and gr. xlv of the ethereal extract of filix mas, ʒijss of gum acacia, and ʒj of fennel-water administered. About 4⅘ inches of the tænia were passed.

The head was very small, the neck fine and quickly terminating in the body. The cuboidal head measured ½ mm. in diameter; and microscopic examination showed the four hooklets placed above and obliquely, and about 122 by 88 mm. The extremity of the head has no proboscis, but is rounded, and is not on a level with the hooks. The links are short and trapezoidal with rounded angles, and become larger toward the tail. The joints or proglottides, always a little broader than long throughout the whole extent of the body, measure about ½ mm. in the smallest height, and about 3 mm. in the largest. The breadth of the proglottides varies from ½ mm. near the neck, to 4 mm. at the caudal extremity, the decrease in size being quite regular from the tail toward the head. The mature joints contain large numbers of ova accumulated at the margin of the joint, which are so numerous as partly to conceal the ovarian canal. This canal is distinguished by its being more of a clavate form, and more slender at the lateral margin of the joints. The ovarian conduit is always on the same side of the joint, and is recognizable by its yellowish color. The genital apertures could not be perceived, nor were the uterine pouches well defined.

The ova, many of which were obtained from the feces of the child, were oval, of an intense yellow color, and measured 58 and 68 mm. in their two unequal diameters. The protoscolex is very distinct, somewhat oval, provided with hooklets. Some of the ova (embryos?) became amber-colored a few hours after being passed in the feces, and were capable of lively irregular movements. The protoscolex is situated in the middle part of the ovum, occupying about a third of the cavity. The ovum is granular in form, structure, and appearance, thus resembling that of the Tænia solium. The shell of the ovum is formed of prismatic layers, giving

it the appearance of a double thickness. The thickness (?) of the shell is a third more than that of the ovum of the Tænia solium.

Parona thinks that there can be but little doubt that this is a specimen of the Tænia flavo-punctata, or flavo-maculata, observed in 1842, by Dr. Ezra Palmer, and examined by Weinland, and afterwards by Palmer and Leuckart. [For a description of a specimen of Tænia flavo-punctata, see the article, by Prof. Leidy, in *The American Journal of the Medical Sciences*, July, 1884.] —*Rezvist. Internaz. di Med. Chir.*, May, 1884.

HYDROBROMATE OF CONIA IN EPILEPSY.—MR. R. N. WOLFENFENDEN reports seven cases of epilepsy treated with hydrobromate of conia. The conclusions he draws from the treatment of these seven cases are—that the drug is undoubtedly serviceable in certain cases, and those in which it fails are cases of convulsious depending possibly on some gross lesion of the brain. The slighter cases were distinctly benefited by it.

The drawbacks to the use of the drug appear in the complaints of headache, and, when in large doses, of giddiness lasting for an hour after taking it, with sometimes a suffusion and congestion of the conjunctivæ. In the doses in which he has given it, there has not been noticed any cardiac or respiratory alteration. It is said that the dose of this drug must not exceed four and a half grains in twenty-four hours, commencing with one and a half grain. In his experience, a child of eight bore one and seven-eighths grain with only headache; a child of seven took one and a half grain per diem, without any complaint; two and a half grains per diem were taken by a female, without complaint; one adult man took three and a quarter grains with impunity. In one case, two grains per diem caused sickness, headache, giddiness, and "weakness" in a young man of eighteen. One and a half to two grains appears to be followed frequently by headache. He thinks the drug deserves further trial, and he hopes to try it more extensively in future. Combined with the constant application of the continuous current, he has successfully treated with it a case of hemichorea. In this case, however, it would be rash to speculate whether the drug, the galvanism, or time was the most effectual in the cure.—*Practitioner*,, June, 1884.

PARTIAL RESECTION OF THE BLADDER.—Following the experiments of Maksimoff, Vincent, Gluck, and Zeller on partial excision of the bladder and suture of the bladder, SNAMENSKJI, of Moscow, has made some interesting researches on this subject on dogs, in order to determine how far one can go in partially excising the bladder without compromising the life of the animal.

In his experiments Snamenskji used from two to four provisory suspension-threads in order the better to fix the bladder during the excision and suture. These were also used in partial resection through the whole vesical wall without, as Vincent has experimentally shown, causing any deleterious effects to the bladder at their seats of insertion. In total resection it was shown that the sutures were injurious in the first experiments, since by the tearing of the threads their points of insertion were pulled open and the animal died of peritonitis. Subsequently the sutures were inserted through the serous membrane alone. For the sutures Snamenskji used catgut, Nos. 0 and 1. Beside the deep (seromuscular) interrupted sutures, he always used superficial glover's sutures, and both sutures were brought by Juillard and Petersen's method up to within two-fifths of an inch of the angle of the wound. For incising the bladder he considers the scissors much superior to the scalpel.

By this method Snamenskji excised the upper half of the anterior wall of the bladder, the whole anterior wall, and a whole bladder with the exception of the part where the ureters entered, and a small part of the anterior wall. All of the animals upon which the last operation was performed died, the majority of peritonitis in three days. Only one dog lived sixteen days. At the autopsy the bladder was found to be pear-shaped, about the size of a walnut; the ureters were dilated to four times their natural size, and the pelves of the kidneys were also dilated. The situation of the sutures could not be seen with the naked eye; only in one place in which the mesentery was somewhat distorted, a thickening of the bladder-wall could be felt. Death took place from uræmia.

The animals upon which partial and total excision of the anterior wall was done lived, with the exception of one, in which case the deep suture was also the glover's. —*Centralbl. für Chir.*, April 5, 1884, and *Lo Sperimentale*, April, 1884.

FIFTY CASES OF TÆNIA.—Dr. Krabbe has published a report of two hundred cases of tænia met with in Denmark. DR. FRIIS, of Tönder, now reports fifty cases coming under his personal observation. Of these, forty-two of the parasites were of the order Tænia mediocanellata, six were T. solium, and two (in children one year old) were T. cucumerina.

The T. mediocanellata was found in thirty-two females and ten males. Doubtless a similar proportion would be found in the cases of Tænia solium if a sufficient number of cases could be collected. It would seem that the woman is ordinarily infected by tasting the raw meat for puddings, etc. Friis found, as did Krabbe, that the majority of infected persons are between the ages of twenty and forty years. None of the remedies used was completely inefficacious, and in the case of the Tænia solium almost any of the usual remedies are likely to succeed except the officinal preparation of the extract of male fern, which seems to be very inefficient. In the cases of T. mediocanellata, however, filix mas was the most efficient of all remedies. The second place must be given to pomegranate root, with or without kousso; but this ordinarily requires several trials, which is not the case with filix mas.

Under the use of the rectified ethereal extract of male fern, in cases of T. mediocanellata, the head came away in 10 cases: the worm disappeared in 6; result unknown in 2; no failures. With the ethereal extract of male fern there were 6 failures. With pomegranate root, the head came away 4 times; the worm 4 times; result unknown 1; failures 5. With pomegranate root and kousso, the head came away 3; the worm 2; result unknown 2; failures 2. With kousso, the head came away 1; failure 1. With psaoria, result unknown 1; failures 2. With kamala, failure 1.—*Nordiskt Mediciniskt Arkiv.*, Bd. xvi. Hft. 1–6, 1884.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

SATURDAY, JULY 12, 1884.

THE TREATMENT OF COMPOUND FRACTURES.

AMONG the noteworthy papers read before the Surgical Section of the American Medical Association, at its recent meeting, is one, by DR. F. S. DENNIS, on the treatment of compound fractures, in which are tabulated 144 cases, without a death from sepsis, and one hundred cases without a death from any cause. Of the entire number 23 are of the skull, 3 of the femur, 58 of the bones of the leg, 12 of the humerus, 14 of the radius and ulna, 9 of the maxillæ, 21 of the bones of the hand and foot, and 4 of the ribs and nasal bones. The favorable results, and the simple measures by which they were obtained, are so conspicuous that they are entitled to a somewhat detailed examination.

Of the 23 compound fractures of the skull, 6 succumbed to shock within forty-eight hours after the injury, so that they were not amenable to any plan of treatment. Of the remaining 17, all of which recovered, 10 were trephined, the lacerated dura mater having been stitched with catgut sutures in one. The wounds were managed openly with carbolic acid, or balsam of Peru.

Of the 61 compound fractures of the thigh and leg, 2 died of shock within twelve hours after their admission, and all of the remainder recovered, despite the fact that 14 underwent amputation, and that in 10 the fracture opened into the knee- and ankle-joints. In one case, indeed, both bones of both legs were comminuted and the bleeding was alarming, while in another both legs and one forearm were broken. Of the 26 fractures of the humerus, radius, and ulna, all recovered save one, which died of shock within twenty-four hours. In 6 amputation was resorted to, and in 7 the adjacent joint was involved. All of the cases of fracture of the maxillæ and other bones terminated favorably.

The treatment adopted by Dr. Dennis includes absolute cleanliness, immediate fixation, and provision for free drainage when necessary. The patient having been anæsthetized, the injured limb is thoroughly scrubbed with soap and warm water, and the wound irrigated with a 1 to 40 solution of carbolic acid, or a 1 to 2000 solution of corrosive sublimate. If the projecting ends of the bone cannot be reduced without too much violence, physiological rest is insured by the subcutaneous section of the tendons of the resisting muscles, aided, if need be, by the removal of the ends of the protruding fragments themselves. Loose spiculæ having been extracted, the wound having been thoroughly washed out with one of the above-mentioned solutions, and the fracture having been adjusted, the opening, if small, is closed with adhesive strips and sealed with collodion, or, if large, is partially united with catgut sutures, a drainage-tube inserted, and covered with iodoform and antiseptic gauze. The entire limb is next enveloped in previously heated Gamgee's absorbent cotton, and the dressing finished with the plaster-of-Paris bandage.

Should the case progress favorably nothing more need be done; but, under opposite circumstances, a fenestrum should be cut over the site of the fracture, and the wound be examined. If the latter be inflamed and the tissues tense, it should be enlarged and washed out with the carbolic or sublimate solution, and be left to suppurate under free exposure to the air, care being taken to keep it absolutely clean and free from all sources of contamination.

The management of compound fractures of the long bones of the extremities, thus outlined, is extremely simple and rational, and the results obtained will compare favorably with the best heretofore recorded. We are unable, however, to understand what Dr. Dennis means when he states that he wishes "it to be understood that I do not undervalue antiseptic surgery," but that the same results are attainable "by other and simpler methods which are within the reach of all," and that "wounds and compound fractures can repair kindly and quickly without danger, though exposed to the air." While it is true that the strict Listerian method was not carried out in his cases, and few practise it now-a-days, it is none the less true that his treatment is, in the strict sense of the term, thoroughly antiseptic, and not the open method of Humphry or James R. Wood. In the majority of his cases, indeed, a fenestrum was not required at the seat of the injury, and when it was, he is most explicit in his directions to enlarge the wound down to the fracture, wash it out with a solution of corrosive sublimate or carbolic

acid, keep the parts absolutely clean, and provide free drainage when necessary. If this is not antiseptic treatment, we have failed to comprehend its principles; and, instead of speaking of the open treatment of compound fractures, we fancy that Dr. Dennis, in recording his great success, would have more correctly described his methods had he called them the antiseptic occlusive and the antiseptic open methods of treating compound fractures.

THE CHOLERA.

THE recent appearance of Asiatic cholera at Toulon and Marseilles, two of the principal Mediterranean ports of France, leads us to sound a note of warning to those whose duty it is to look after the health interests of our country.

The history of this disease in the past would seem to warrant the prediction of Dr. Koch: "It will reach Germany; it will go everywhere." Its march through India every third, sixth, ninth, and twelfth years, following the pilgrimages to Juggernaut, Hurdware, and other shrines, and its periodical twelve-year visitation to this country, render it quite probable that the disease has started on its course and may reach our shores at any moment. In the last epidemic of 1873, cholera visited the United States before it appeared in Paris.

Then there were many sources of infection—it was first brought to New Orleans by a Bremen bark, and developed in the case of a man employed in unloading her cargo (a native of Pensacola who went to New Orleans for employment). But the larger number of cases were imported directly through New York City on non-infected vessels, but the disease was not developed until the personal effects of the victims had been unpacked at their destination. This was shown in the three distinct outbreaks at widely remote parts of the United States, where the effects of emigrants from Holland, Sweden and Russia were unpacked at Carthage, Ohio, Crow River, Minnesota, and Yankton, Dakota, where, within thirty-six hours thereafter, the first cases of the disease appeared. All these emigrants touched at Liverpool, where they were transferred to vessels bound for the United States.

It will be seen by the foregoing that infected ships are not the only sources of danger, and that the safety of the country greatly depends upon a prompt notification by telegraph of the departure of emigrants bound to the United States from any port in Europe, or of merchandise from infected districts. With this information, and the knowledge we now have of the infection, it is believed that the disease can be kept within very narrow limits—in fact, confined to the immediate vicinity of those who are the carriers of the disease.

By employing 1. Immediate telegraphic notification from Europe upon the departure of emigrant ships from foreign ports; 2. Rigid inspection of such vessels, including thorough disinfection of all emigrants' clothing and baggage upon arrival at United States ports; and 3. Perfect local cleanliness in every port, town, and country village; there need be no fear of the cholera becoming epidemic in this country. There may be a few sporadic cases, but they should occasion no alarm, as the disease is everywhere admitted to be a filth infection, and its antidote is cleanliness.

The National government, through the State Department is obtaining daily telegraphic notification from Europe relative to the progress of the disease, and the departure of immigrants to the United States, and a circular to Collectors of Customs, prepared by Surgeon-General Hamilton, has been issued from the Treasury Department, "requiring evidence that none of the baggage of immigrants or returning travellers has been shipped from the infected districts since June 20, 1884, and a certificate of the local quarantine officer, to the effect that no danger to the public health need be apprehended from allowing the landing of any passenger's baggage, may be accepted as entitling such traveller or immigrant to land his effects."

In addition to these precautions, the President's "Epidemic Fund," under control of the Marine-Hospital Service, is being employed to prevent the introduction or spread of the disease, and to establish quarantines at points of danger. Three United States quarantine stations are now equipped for the work—one at Ship Island in the Gulf, a second in Sapelo Sound on the coast of Georgia, and the third at the mouth of Chesapeake Bay.

It only remains, then, for our local health authorities, and sanitarians generally, to keep alert, to thoroughly and systematically organize a force of inspectors whose duty it shall be to daily patrol the alleys and by-ways of our cities and towns, and follow up their inspections by having all filth and unsanitary matters removed or corrected. Municipal cleanliness, isolation hospitals, and national quarantines, will keep our country free from all epidemics.

MILK SECRETION AS AFFECTED BY SPAYING, BY EXERCISE, AND BY CERTAIN MEDICINES.

MR. LLOYD F. ABBOTT recently read before the Suffolk District Medical Society (*Boston Med. and Surgical Journal*, April 3 and 10, 1884), an interesting paper on the increase of milk secretion resulting from spaying cows.

Spaying cows for the purpose of securing a constant supply of milk, uniform in quantity and quality, has probably not been done in this country outside of Massachusetts. Mr. Abbott's attention was

directed to the subject by a translation from a French work in 1880; but he learned that the Hon. Josiah Quincy had had the operation performed at his farm twenty years before.

The results of Mr. Abbott's experience are that the operation is not dangerous, and that it increases the flow of milk and improves its quality. The operation may be done by abdominal, or by vaginal incision—the former seems to be preferred—and thus veterinary surgery recognizes the same methods that have been used in the human subject, abdominal and vaginal ovariotomy. But the removal of the ovaries once they are reached, is a much simpler operation in the cow than in the human female—only the thumb-nail being needed in tearing away the organs, and no ligatures are required.

The testimony of the medical gentlemen who discussed the subject when the paper was read, was decidedly in favor of the beneficial influence of the operation upon the secretion of milk. It is claimed that the amount given by a spayed cow will remain the same all her life. This certainly is a matter of great interest and importance; and should it be confirmed by further experience, we do not doubt that this operation will become quite common.

While referring to the matter of spaying cows in relation to the supply of milk, we may also note some investigations of MUNK, given in a recent number of the *Archiv f. Anat. und Phys.*, as to the influence of exercise upon the milk secretion of cows. Munk acknowledges that Schmidt-Mülheim is correct in his statement as to excessive exercise lessening the quantity of milk for these reasons. In exercise of this sort the blood current is directed from the gland apparatus to the muscles, there is also a great consumption of material, and chewing the cud is interfered with. He, however, disputes the statement that cows must be kept at absolute rest, in order that the secretion of milk shall attain the maximum. His own observations prove that, as in the nursing woman, moderate exercise increases the secretion of milk by changes in respiration, in circulation, and in digestion, and, hence, the general condition of the animal is better, the appetite greater, and its nutrition improved. The increase in the milk of cows allowed moderate exercise, is not merely in its watery portion, but in the butter and casein.

"The National Dispensatory," p. 1086, states that the mammary secretion is diminished by atropia, and increased by pilocarpin. The recent studies of HAMMERBACHER, *Pflüger's Archiv f. Physiologie*, show that this statement, especially as to the action of pilocarpin, needs qualification. He finds that after its administration, atropia causes a considerable reduction in the milk mass, but it is richer in solid elements, especially fat, and in seven hours after its administration the secretion becomes normal. Pilocarpin causes a reduction in the milk mass, and the milk is poorer in solid constituents than normal milk; the effect lasts longer than that of atropia, and is to be attributed to the disturbance caused in the general health; the presence of pilocarpin in the milk has not been ascertained.

PARTIAL LARYNGECTOMY.

AT the recent meeting of the German Surgical Association, HAHN, of Berlin, recorded five cases of laryngectomy for carcinoma, the entire larynx having been removed in three, and one-half of that organ in two. Of the former, two died of suppurative bronchitis and pneumonia in the fourth and fifth week, and the third was still living at the end of three months. Both of the latter recovered and were free from recurrence, respectively, at the end of three years and a half and nine months. They were wearing a simple canula, and were comfortable, and made themselves so readily understood that they refused to have the wound closed.

Hahn is a strenuous advocate of removing only one-half of the larynx where the limited extent of the disease admits of it. Total extirpation has resulted in twenty-four deaths out of fifty-two cases, while removal of one-half of the larynx has terminated fatally once out of eleven cases. Not only is the latter operation more safe, but it is less frequently followed by recurrence, and the functional results are so much better that the canula can be dispensed with in the majority of instances.

In the discussion elicited by the reading of the paper, Hahn found two warm supporters of his views in Schede, of Hamburg, and Küster, of Berlin. Schede's patient was living eighteen months after excision of the right half of the larynx for carcinoma. He had ceased to wear the canula for nine months, and his articulation was distinct. Küster's operation was for sarcoma, but the speech was hoarse and less clear than in Schede's case. Unfortunately, the time that had elapsed since the operation is not stated.

THE paper on "Branny Foods" prepared by DRS. N. A. RANDOLPH and A. E. ROUSSEL, and read by the former before the College of Physicians of Philadelphia, on June 4th, is a valuable contribution to our knowledge of this subject. That the outer three of the four bran coats of the wheat grain contain little or nothing that is nutritious except the salts, and that the rapid peristalsis which they excite when ingested as food interferes with the absorption of the true nutritious substance of the grain, will be a surprise to many. But these facts seem, nevertheless, to have been shown by the authors.

Even the salts, which the authors acknowledge to be lost when the bran coats are removed, are

not essential in a mixed diet of white wheat bread with succulent vegetables, in which these elements abound. Hence the lovers of white bread need not feel in the future that they are such grievous offenders against the laws of health.

REVIEWS.

SEVENTH ANNUAL REPORT OF THE BOARD OF HEALTH OF THE STATE OF NEW JERSEY. Pp. 391. Trenton: 1883.

THIS report, which has just been presented to the Governor of New Jersey, is well calculated to maintain the high standing of the previous reports issued by this Board.

The volume opens with a recital of the work done by the Board during the year 1883, written by the Secretary, that veteran sanitarian, Dr. Ezra M. Hunt. His report contains many valuable suggestions.

The record of vital statistics for the State shows a mortality of 23,310 for the year ending July 1, 1883, which is a considerable decrease from previous years, while the marriages and the births have increased.

The Secretary says that "a review of the past year assures us that both the public and the local health authorities are realizing the great significance of health and care, and the value of those improvements which secure good water, proper disposal for decomposable substances, good houses, cleanly habits, and chances for employment deprived of all avoidable insanitary conditions. Several cities and towns have entirely modified their health administration, and others are so agitating the need as to be sure, eventually, to bring about desired results." A truly commendable and encouraging report.

The space at our command does not warrant a detailed account of the many valuable essays in the report, but we shall briefly note a few of the more prominent and interesting papers.

The Secretary contributes an essay on "Health in the Home and its Surroundings," which condenses into a few pages all the positive knowledge we have concerning sanitary house construction, ventilation, heating, drainage, and sewerage. Especial care is taken to point out the necessity of properly selecting and arranging the site. This article will well repay perusal.

Dr. David Warman, of Trenton, has an article on "Modes and Places of Interment," which is not so erudite or diffuse as the recent work by Dr. Stephen Wickes on a similar topic, but calls attention to the danger of interment in built-up portions of cities, and especially the peril of using old cemeteries for building sites.

There is no topic of more importance than the sanitary condition of our health resorts, and the Board has endeavored in its sanitary inquiries to awaken an interest in the subject. The article on this subject is disappointing, in that it does not tell specifically the danger to be feared in the summer resorts in the State. The Atlantic coast may be said to be lined with summer boarding places, and the thousands of people from Philadelphia, New York, and more distant places should be assured by competent authorities as to the healthfulness of these resorts. Most of the seaside hotels are but commercial ventures, hastily and cheaply constructed, and the water-supply and sewerage systems are not of the best. The State Board has, however, made an attempt to indicate in mild language where the more healthful resorts may be found, and where the more dangerous places are. We regret that there is nothing in this part of the report to which physicians contemplating a change of climate for patients may turn for information, and we hope that in the future the Board will devote more attention to this very important branch of their work.

The charitable and penal institutions of the State have been inspected, and in the synopsis given by the Board we find much to approve.

School hygiene comes in for a large share of space, and an exceedingly interesting and suggestive paper is contributed by Principal Green, of Long Branch. His is a practical article.

The diseases and dangers incident to trades and occupations are outlined by the Secretary.

In the summary of reports from local health boards we find that these bodies are in many places doing excellent work. The report from the Paterson local board is singled out as worthy of example.

Thirty-five pages are devoted to a report from the Council of Analysts and Inspectors, from which we learn that the illuminating oil has been been bettered by the system of inspection, and that the State milk inspector is encouraged by an improvement in the quality of the milk sold in the State. Prof. Cornwall furnishes an excellent article on malt beverages. His analyses show that beer and ale are not adulterated, and that the percentage of alcohol varies from 4.4 to 8.6 in these malt liquors.

A list of physicians who have complied with the State law, and who have registered a copy of their diplomas in the office of the County Clerk, takes up some thirty-four pages. To this list we shall refer again.

The Medical Superintendent of Vital Statistics publishes his annual report, together with quinquennial tables of mortality for the five years ending June 30, 1883.

We have thus roughly outlined the more important articles in this very interesting report, which should be read by all who wish to increase their store of knowledge concerning sanitary science.

SOCIETY PROCEEDINGS.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, June 4, 1884.

THE PRESIDENT, J. M. DA COSTA, M.D., IN THE CHAIR.

DRS. N. A. RANDOLPH and A. E. ROUSSEL presented the following

STUDY OF THE NUTRITIVE VALUE OF BRANNY FOODS.

From an economic standpoint the question of the nutritive value of bran is one of great importance, for the removal of this portion of the wheat implies a loss of from seventeen to twenty per cent. in the weight of the grain. In spite of this loss, which necessarily renders

white bread more expensive than that made from whole wheat flour, even the poorest inhabitants of most civilized countries where bread is not the staple food, insist upon eating the bread made from the finer grades of flour. A tendency so widespread as this would apparently indicate the unconscious summation of the experiences of many generations, and go far toward proving the propriety of such a selection.

The use of flour representing the entire wheat grain has, however, been long and ably advocated; the reasons given for the retention of bran being that its removal entails the loss of:

I. "Nutritive salts" (Nährsalze of Liebig).

II. Carbohydrates.

III. Proteids, notably gluten.

The facts, also, that branny foods in common with many others will spur an atonic bowel to activity, give due bulk to its contents, and induce the passage of stools of the normal or feculent consistency are noteworthy, but their further consideration is beyond the limits of the present paper. The other reasons for the retention of bran in wheat flour will be discussed seriatim.

I. The fact that fine flour contains a much smaller percentage of salts than does either bran or the whole wheat—a fact evidenced by the relatively small amount of ash which it yields, forms the basis of the theory of Liebig,[1] that in the removal of bran nutritive salts of value are lost. The investigations of Meyer[2] and Foster[3] are often cited as showing that, after the removal of bran, these salts are still present in quantity sufficient for the needs of the economy.

Our experiments upon young pigs, described further on, show that although survival is quite possible upon an exclusive diet of bread from white flour, growth is much more active upon a diet of bread containing a greater amount of inorganic matter. It is possible that Liebig's estimate of the needful amount of inorganic matters was too high, but it is equally noteworthy that there is a tendency on the part of late writers to give insufficient prominence to the importance of these elements of food. It may not be out of place here to mention a striking illustration of the absolute necessity for inorganic salts in the fluids of the economy, as recorded by Dr. S. Ringer.[4] This observer found that while minnows were kept in ordinary tap water they would live for weeks unfed. When, however, they were placed in distilled water they died on an average in four hours and a half. Further, that in a rude imitation of spring water, made by the addition to distilled water of potassium and calcium chlorides, and of sodium bicarbonate, the fish lived on an average about two weeks. Study of the factors in the experiments showed that death was due to a diminution of salts in the economy of the fish. That such diminution, even when very slight, could result fatally, was shown by an analysis of the distilled water after the death of the fish; traces only of inorganic matter being found.

II. The loss of carbohydrates involved in the removal of bran, appears at first sight not inconsiderable, as it amounts to about twenty per cent. of the carbohydrates present in the entire grain. The members of this group represented in bran are starch and cellulose. The former is present in extremely small amount, while the latter, as has been proven by the experiments of Donders,[1] Mulder,[2] and Poggaile,[3] is digestible in any noteworthy degree[4] by the herbivora only. The observer last named subjected a given weight of dry bran to the successive actual digestions of two dogs and one hen, and, thereafter, was able to recover over sixty-five per cent. of its non-nitrogenous constituents. The loss in cellulose was probably much less than that here indicated, for we have found that during the maceration of bran in the digestive tract, certain portions become detached from the main flake, and are with the greatest difficulty recovered.

III. Wheat bran contains a considerable but varying proportion of nitrogenous compounds, averaging however about 14 per cent.[5] This fact has permitted the continued existence of two widely credited assumptions: (*a*) That this nitrogen exists in albuminoid combination, or, in other words, is in a nutritious form; and (*b*) that the proteid matter of wheat is contained almost exclusively in specific cortical cells of the grain—the so-called "gluten cells."

(*a*) Nearly all the existing estimates of the proportion of proteids in food-stuffs are based upon the hypothesis that all of the contained nitrogen is present in some albuminoid combination. The percentage of nitrogen in a given food is therefore ascertained, multiplied usually by either 6.5 (Payen) or 6.33 (Ritthausen) and the result recorded as the percentage of proteid matter. It has lately been conclusively proven that nitrogen in non-albuminoid combination, *i.e.*, in compounds not capable of affording nourishment to any higher organisms, is present in many food-stuffs, and especially in those of vegetable origin. As a case in point, may be mentioned the analyses of Wigner,[6] in which it is shown that of the total nitrogenous matter of the entire wheat grain, 87.9 per cent. is coagulable, *i.e.*, distinctively proteid. Of the bran only 42.4 per cent. of its nitrogenous compounds are coagulable, whereas, in the flour, 89.7 per cent. of these bodies come under the head of true proteids. Yet more marked instances of the inaccuracies attending the ordinary methods of estimating proteids have become evident in the course of researches by Schulze and Barbieri,[7] who find that of the entire nitrogen of the potato but 56.2 per cent. enters into the composition of albuminoid matter, while

[5] Dempwolf, Ann. d. Chem. u. Pharm., vol. cxl. p. 343. His figures, of interest here, are as follows: The amount of nitrogenous matter in the whole wheat was 14.35 per cent. The amount varied in the different grades of white flour from 11.01 to 15 56 per cent. The nitrogenous matter of the two grades of bran made from this wheat was respectively 13.93 and 14.06 per cent.

[7] Quoted by Voit, Hermann's Hdb. d. Physiol., vol. vi. p. 462.

in the fodder beet only 20 per cent. of its contained nitrogen is thus combined, the remaining 80 per cent. aiding in the formation of amides, nitrates, and ammonia. It is evident from these facts that estimates of the nutritive value of branny and other foods, based upon the percentage of nitrogen present, must be received with caution.

(*b*) The term "gluten cell" is, through a widespread misapprehension, applied to the cells constituting the fourth layer (Parkes) of the wheat grain. These cellular elements exist usually in a single stratum, as irregularly cuboidal bodies in each of which, surrounded by a dense and laminated cellulose wall, is seen the semi-opaque granular contents. Upon the addition of reagents, especially in the form of caustic alkaline solutions, there is almost constantly noticeable a differentiation of the contents strongly suggesting the presence of a nucleus. Under these conditions, also, a coalescence of many of the individual granules forming the contents occurs with the formation of several highly refractive spheroidal bodies, an appearance which has led Payen (as quoted by Dr. Richardson) to use the name oléifères as a synonym for the cellular constituents of the fourth coat. The hypothesis that the cells of this layer are the chief gluten-bearers of the wheat grain is usually attributed to Donders.[1] The return of bran to flour was at about the same period also advocated by Millon and Mége Mouriès.[2]

From this time on, with but few dissenting voices, the "gluten cell" has been generally spoken of as the index of the nutritive nitrogenous matter[3] of the wheat grain, while the central portion included within this layer, and constituting fully 80 per cent. of the grain, has been popularly regarded as being made up almost exclusively of cellulose and starch, and attempts have even been made to estimate the nutritive value of certain cereal food-stuffs by a microscopical determination of the proportion of "gluten cells" present.[4]

The manifest impropriety of such methods has of late been strongly emphasized by Prof. Richardson, of this city, and Prof. Leeds, of Hoboken. The credit of the first disproof of the exclusive limitation of gluten to the cells of the fourth layer, is probably due to Schenk,[1] who treated sections of wheat grain with Millon's reagent, a pink coloration of the endosperm resulting. This coloration was most vivid at the periphery, indicating a gradual condensation of the proteid constituents of the grain as the cortex was approached. The same writer found "no coloration of the 'gluten cells' as a result of this reagent," an observation which we cannot confirm; for, apart from the readily demonstrable slight coloration of the contents of "gluten cells" after the application of Millon's reagent, it is more than difficult to conceive a cell, however specialized, which shall exhibit no proteid matter as a portion of its contents. Schenk also noted in artificial gastric digestions of sections of wheat, that the starch granules which (to a greater extent) fill the cells of the central portion of the grain, became detached, and from this fact deduced the just proposition that the starch granules lay imbedded in some albuminoid substance. In a study of the distribution of gluten within the wheat grain,[2] the senior writer has described several methods for the ocular demonstration of gluten, in very considerable amount, in that portion of the grain included within the fourth layer, and entirely independent of the "gluten cells." The methods were as follows:

If whole wheat grains be macerated in water, to which a few drops of ether have been added to prevent germination, they will, in a few days, become thoroughly softened, and the contents of each grain may then be squeezed out as a white tenacious mass.

Examination of the remaining bran shows the "gluten cells" undisturbed, closely adhering to the cortical protective layers.

By now carefully washing the white extruded mass, the major part of the starch may be removed; and, upon the addition of a drop of iodine solution, microscopic examination shows numerous networks of fine yellow fibrils, still holding entangled in their meshes many starch granules, colored blue by the iodine.

In carefully washed specimens, the sponge-like networks are seen to retain the outline of the central starch-filled cells, and evidently constitute the protoplasmic matrix in which the starch granules lay. Upon gently teasing such a specimen under a moderate amplification, the fibrils will be seen to become longer and thinner in a manner possible only to viscid and tenacious substances—a class represented in wheat by gluten alone.

An eminently satisfactory proof of the proteid nature of these central networks may be obtained by heating the specimen in the solution of acid nitrate of mercury (Millon's reagent), when the fibrils will assume the bright pink tint characteristic of albuminoids under this treatment. The results of the application of the xanthoproteic and biuret reactions are equally conclusive, but more care is required in the use of these proteid tests, and the resultant differentiation is not so clear. Reticuli, similar to those above described, but much broken and consequently far smaller, may be seen upon close examination, scattered throughout fine white flour, without the use of any reagent.

[2] Comptes Rendus, vol. xliv. p. 47.

[3] By general consent the albuminoids of the wheat grain are grouped together as gluten, which is, however, further separable into gluten-fibrin, gluten-casein, gliadin, and mucedin, proteid bodies practically equal in nutritive value, but differing in certain physical properties, notably that of solubility. It must therefore be borne in mind that in all methods of separating gluten from the other constituents of the grain, its (relatively small) soluble portion is removed with the starch, and that any estimate of the quantity of gluten based upon such methods will probably be below rather than above the actual amount. Ritthausen (Die Eiweisskörper der Getreidearten, 1872) believes that a certain amount of true albumen should be included with the constituents of gluten just mentioned. An observation of Denis (Mémoire sur le sang, 1859), confirmed by Hoppe-Seyler (Med. Chem. Unters. 1867) and Weyl (Ber. d. deut. chem. Ges., xiii. 10, 1880,) demonstrates that a portion of the proteids of the cereals exists in the form of a globulin. Thus, the observer last named has shown that in wheat flour treated with a 15 per cent. solution of sodium chloride, no formation of gluten occurs. We have found that bran when macerated in 15 per cent. salt solution, yields a considerable amount of proteid matter precipitable by nitric and picric acids. We incline to believe, however, that this is not a true albumen. (See Vines, Journal of Physiology, vol. iii. p. 93.)

[4] E. Cutter, M.D., Galliard's Med. Journ., Jan. 1882.

[1] Anat.-Physiol. Utersuch., p. 32, Wien, 1872.

[2] Randolph, Proc. Acad. Nat. Sci. Phila., Dec. 11, 1883, p. 308.

In even the thinnest sections of the wheat grain, the gluten of the central portion is always masked by large numbers of starch granules. These may to a large extent be removed by immersing the section for a short time in liquor potassæ, with subsequent careful washing. The alkali effects the hydration and partial solution of the starch; but, if its application be too long continued, the gluten will also be dissolved. This treatment is well adapted to show the rather dense gluten networks usually found adherent to bran immediately below the fourth layer.

The most satisfactory method of studying the distribution of gluten in sections of wheat, is that of artificial salivary digestion. If the section be gently boiled for a moment to hydrate the starch, then transferred when cool to filtered saliva, and maintained for from half an hour to an hour at a temperature of about 98° Fahr., all the starch will be dissolved, while the insoluble proteid and other constituents will remain *in situ* and entirely unaltered. The same result may be obtained from a somewhat more prolonged digestion of the unboiled section. A section of wheat grain thus treated will exhibit throughout its entire central portion close-meshed gluten networks, which become slightly denser towards the cortex of the grain. The proteid character of these reticuli is here, as in the first method, susceptible of micro-chemical demonstration. Upon the application of Millon's reagent to such a section, a relatively very faint coloration, indicating the presence of albuminoids, is noticeable in the "gluten cells," while the gradual condensation of the gluten of the endosperm, as the fourth layer is approached, is evident even to the unaided eye.

The fact that the gluten networks become denser towards the periphery of the endosperm, together with the presence of non-albuminoid nitrogenous compounds in the perisperm, explains the notable percentage of nitrogen found in bran as ordinarily roughly removed.

The small proportion of albuminoids present in the cells of the fourth layer as evidenced by their feeble response to the proteid tests, together with the very considerable quantity of gluten which we have shown to exist in the central four-fifths of the grain (*i. e.*, the portion lying within the fourth layer) justifies us in the conclusion that by far the major portion of the nutritious nitrogenous matters exists in entire independence of the "gluten cells."

The difficulties which attend the complete isolation of these cells, however, have as yet rendered impossible any accurate estimation of the proportion of their proteid contents. Admitting for the moment that the "gluten cells" contain albuminoids in any noteworthy amount,[1] there are yet present conditions which seriously affect, if they do not entirely nullify the nutritive efficiency of this portion of the grain.

The first of these conditions is the presence of the rough bran scales which, by increasing peristalsis, so hasten the passage of the entire intestinal contents that complete digestion and absorption are prevented. The second is that owing to the dense cellulose walls of the "gluten cells," their contents are practically unaffected by the digestive juices. The fact that the presence of branny scales in the digestive tract prevents the thorough digestion of the intestinal contents and induces the passage of feces containing a considerable excess of undigested nitrogenous matter is fully attested by the observations of Meyer and Rubner.[1] Edward Smith[2] has also closely studied the ecomonic phase of this subject, and reports most unfavorably upon the use of branny foods, stating that the diminished absorption of nutritive matters, entailed by their use, more than counterbalances the (apparent) gain in cheapness. Of interest in this connection is the observation of Fr. Hofmann[3] who noted that the amount of feces passed upon a meat diet was remarkably increased by the addition of cellulose to the food taken.

The feeble response of the "gluten cell" to reagents and digestive juices, has been noted by several observers. Thus Donders[4] states that these bodies are digested by the herbivora, but not by dogs or man. Similar results are recorded by Poggiale,[5] and for domestic fowls by Meissner and Flüge.[6] J. Lehmann[7] records the feeding of pigs for thirty-two days on bran which contained almost no flour, with a nearly negative gain in weight, although the bran contained 15.5 per cent. of nitrogenous matters.

The ability of herbivora to digest "gluten cells" and similar bodies, is probably due to the relatively powerful amylolytic ferments of their digestive fluids, for it has been demonstrated that pepsin is unable to traverse cellulose.[8] It has also been shown by one of us[9] that the cells of the fourth layer are to all appearance entirely unaffected by prolonged artificial digestions—salivary, gastric, and pancreatic, and further, that their contents were but little changed, and their walls in no-wise disintegrated by immersion for some days in strong acids and alkalies.

Lately, however, in the course of an admirable paper upon the nutritive relations of gluten, Rubner[10] has stated that although branny foods increase the amount of nitrogen in the feces, fully three-fourths of the nitrogenous matter of bran is digested. In the bran used there was present 4 per cent. of nitrogen, "equalling 25 per cent. albuminoids," while in the bran obtained from the feces of the persons under observation only 0.9 per cent. of nitrogen was obtainable. We hesitate in criticising the results of so able an observer, but it seems to us that there were two sources of error in this portion of his investigation. In the digestion of bran the free, adherent gluten, which properly belongs to the more central layers, is of course readily dissolved with

[1] Apart from the statement of Schenk, above cited, the entire absence of gluten in the cells of the fourth layer has been latterly affirmed by Mége Mouriès, who is quoted by Payen (Substances Alimentaires) to the effect that these cells are "filled with nitrogenous substances of which gluten is not at all one." He finds the cells in question to contain in addition to the salts of magnesium, lime, and potash, a peculiar diastatic ferment, cerealin, whose function is the transformation of the starch of the grain into dextrine and glucose for the nourishment of the germinating seed.

a consequent reduction in the nitrogen of the bran. Apart from this, however, a loss in nitrogen is to be expected from the diffusion of nitrogenous crystalloids; further, the "gluten cells" become so separated from the true bran, during their maceration in the intestinal contents, so that it is nearly, if not quite, impossible to recover them.

In order to satisfy ourselves regarding the digestibility of the cells of the fourth coat, we have subjected bran with its adherent "gluten cells" to actual digestion by twelve well-nourished adults, six males and six females. These twelve persons were selected from a larger number by excluding all whose feces exhibited under microscopic examination any inefficiency in the amylolytic and proteolytic digestive ferments as evidenced by the presence of starch or muscle fibre in more than a minimal amount. Sources of error arising from individual peculiarities having been eliminated by the number of persons under observation, and the best conditions for digestion having been obtained, these persons then received daily for three days, in addition to their regular food, one ounce of thoroughly boiled bran. Their feces for the last two days of the treatment were submitted to close microscopical examination, with results so nearly uniform as not to require tabulation. In every case the number of "gluten cells" present was more than sufficient to render a diagnosis of the food taken a matter of great ease. In two-thirds of the cases no evidences of disintegration of any of the cells could be found upon repeated examination of many fields from each specimen. In four cases a small proportion (less than ten per cent.) of the numerous cells examined, showed evidences of having been affected by the digestive process, the cell contents having become lighter in color and less opaque. If, however, any true digestion of the cells had occurred, it is evident that many of these elements in different stages of disintegration would have been seen.

As a rule, we found that the several layers of the bran presented an appearance, not of having been digested, but simply of having been subjected to prolonged maceration. Thus the three coats of the true bran while entirely unchanged, were frequently found separated from each other. We had expected to find the fourth layer closely adherent to the third, as is the case in dry bran, but in the majority of specimens these two coats became separated, and occasionally large sheets of "gluten cells," to all appearances perfectly normal, were seen. As a rule, however, that portion of the fecal mass representing the meal at which bran was taken[1] was found to contain these thick-walled cells in nearly every field.

A study of the nutritive relations of a given food may be approached from three sides: First, from that of the exact chemical composition of the food, a knowledge absolutely essential to any scientific scheme of diet. Second, from that of the various excretions of the individual or animal upon the diet in question; and, third, from the more clinical standpoint of study of the effects exerted by a given diet upon the growth and nutritive processes of the organism under observation. After an examination of branny food in the light of the first two methods, we attempted its study by the third. To this end six young pigs of the same litter, and all in fair health, were weighed and placed under the same conditions in pairs, in three separate bins. Those in the first bin daily received bread especially made from whole wheat flour, in amount corresponding to one-fourth pound of dry bread each. To those in the second bin was given a corresponding amount of bread made from wheat whose three external coats only had been removed. The pigs in the third bin received the best white bread in amount corresponding to the standard above mentioned. A sufficient (fixed) quantity of water was given twice daily. The following table shows the weight of each pair at the beginning of the observation, and at the end of respectively ten and thirty-two days thereafter:

Bin.	Age	Food.	Joint weight March 6.	Joint weight March 16.	Joint gain 10 days.	Joint weight April 6.	Joint gain 32 days.
	weeks.		lbs	lbs	lbs.	lbs.	lbs.
I	6	Bread from whole wheat	24.5	29.0	4.5	33.25	8.75
II.	6	Brown bread from decorticated wheat	24 75	28.25	3.5	34.50	9.75
III.	6	White bread	25.25	27 25	2.0	33 0	7.75

Comparison of these weights exhibits curious and apparently contradictory results, viz., that during the first ten days the gain was greatest in the pigs fed upon whole wheat bread, whereas, at the end of thirty-two days of such feeding the gain was most pronounced in the pigs fed upon bread made from wheat whose three outer coats had been removed. The cause of this variation in results is not far to seek. At the commencement of the experiments the animals were small, and the food given was in each case more than sufficient to replace the waste in both the tissues, and circulatory fluids. Even the pair fed upon bread containing the innutritious and waste-inducing bran, digested and absorbed sufficient proteid matter to supply the needs of the tissues, and normal growth was also favored by the presence of a bulky intestinal contents of a mechanically stimulating nature and also by the nutritive salts which were present in this bread in larger amounts than in the others. On the other hand, at the end of the thirty-two days, the animals had notably increased in size; the food given was then barely sufficient for the needs of the economy, and any conditions impeding its complete digestion and absorption produced a notable effect upon the rate of growth of these young animals.

It must be borne in mind that these experiments relate only to the value of the different breads when taken alone to the exclusion of other foods. The experiments of Rubner before cited leave no doubt that a white bread contains more assimilable nutriment than does one made from the whole wheat, but this does not render it a desirable food-stuff for exclusive use. On the contrary, a weaned, but still quite young omnivorous mammal thrives better upon an exclusive diet of bran bread than on white, and, presumably, because

[1] We did not find it needful to give with the bran any coloring matter to differentiate in the feces the meal at which it was taken, as the scales of bran were always a sufficient index. When requisite, such differentiation may readily be obtained by the method of Cramer (Zeitschr. f. Physiol. Chem., vol. vi. p. 354), or that of Rubner (l. c.).

the earthy and alkaline salts are present in greater abundance in the former, and, also, because the indigestible constituents tend to give to the intestinal contents that bulk and consistence which are essential to the hygiene of the digestive tract. But, as has been shown by Edward Smith and others, the branny scales are needlessly irritating, and unduly hasten the passage of food[1] but partially digested and absorbed. The end which popular hygiene attempts to effect by the retention of bran in breadstuffs can be better attained by other means. Thus the nutritive salts of food so frequently lost in ordinary methods of preparation are readily restored by the concentration of the liquor in which meats and vegetables are cooked, into a soup stock, as is practised in almost every French kitchen. Again, the various fresh green vegetables used as salads, yield in abundance these inorganic food-stuffs, the presence of which we have seen is indispensable to normal tissue activity. A further advantage of these and other succulent vegetables lies in the fact that their cellulose, while efficient in giving proper bulk and consistence to the stools, is, as compared with bran scales, soft and unirritating to the digestive tract.

From the facts, old and new, which have been presented, the following deductions appear to us justifiable:

I. The carbohydrates of bran are digested by man to but a slight degree.

II. The nutritive salts of the wheat grain are contained chiefly in the bran, and, therefore, when bread is eaten to the exclusion of other foods, the kinds of bread which contain these elements are the more valuable. When, however, as is usually the case, bread is used as an adjunct to other foods which contain the inorganic nutritive elements, a white bread offers, weight for weight, more available food than does one containing bran.

III. That by far the major portion of the gluten of wheat exists in the central four-fifths of the grain, entirely independent of the cells of the fourth bran layer (the so-called "gluten cells"). Further, that the cells last named, even when thoroughly cooked, are little if at all affected by passage through the digestive tract of the healthy adult.

IV. That in an ordinary mixed diet, the retention of bran in flour is a false economy, as its presence so quickens peristaltic action as to prevent the complete digestion and absorption, not only of the proteids present in the branny food, but also of other food-stuffs ingested at the same time; and,

V. That inasmuch as in the bran of wheat as ordinarily roughly removed, there is adherent a noteworthy amount of the true gluten of the endosperm, any process which in the production of wheaten flour should remove simply the three cortical protective layers of the grain, would yield a flour at once cheaper and more nutritious than that ordinarily used.

[1] An observation worthy of mention in this connection is that of Rubner, who finds that while the presence of much woody fibre and harder cellulose in the intestinal contents induces the passage of stools containing an excess of undigested proteid foods, the absorption of fats under the same conditions is not materially affected.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, May 28, 1884.

THE PRESIDENT, WM. H. WELCH, M.D., IN THE CHAIR.

DR. THEOPHILUS PARVIN presented a

REPORT OF THE OBSETRIC DEPARTMENT OF THE PHILADELPHIA HOSPITAL FOR THE QUARTER ENDING APRIL 30, 1884.

He said: During my term of service at the Hospital seventy-two women were confined; this number, however, includes two cases of premature labor, and one of miscarriage at six months and a half; there was one case of twins. In sixty-nine cases the vertex presented; presentation of a foot, of the breech, and of the shoulder, each occurred once; the presentation in the case of miscarriage is not given. Forty of the seventy-two mothers were primiparæ. Of seventy-three children born, thirty-nine were females, and thirty-four males—a preponderance of female births which is at least remarkable.[1] Fifty-one of the mothers were white, twenty-one black. The average weight of the white children was seven pounds and a little more than two ounces; that of the colored children, seven pounds thirteen ounces and a fifth; there was thus a difference of eleven ounces in favor of the latter. The heaviest child was a white one, its mother a primipara; its weight was nine pounds and twelve ounces. Comparing the difference between white male and female children, it was a little more than one pound;[2] while the corresponding difference in black children was only two ounces and one-fifth. Of course, the number of cases observed is too small to allow a positive conclusion, but it suggests that the difference between the two sexes in the white and in the black races in regard to weight of the new-born is much more marked in the former than in the latter. If the results obtained in these limited observations should be confirmed by more extensive ones, we would have a race distinction which is in perfect correspondence with a known ethnological law.

As to the average weight of the new-born, I may repeat what has been published elsewhere. At my request, Dr. Phillips found, from examination of the Philadelphia

[1] The general relation between female and male births is 100 to 106. Illegitimacy slightly lessens this proportion, that is, increases the number of females born; and this is a factor adding to the number of female births at the Philadelphia Hospital, for illegitimate births are there the more numerous, but still it is not sufficiently potent to entirely reverse the law. This abnormal disparity between male and female births is not a mere accident of the three months, for taking all the births of 1882 and 1883, and adding those of the first quarter of 1884, I find the number is 371, and of these 173 were males, and 198 females. It would be interesting to examine the hospital record for a long series of years, and ascertain if this disparity is the same; and this it is my intention to do.

While referring to the normal relation between male and female births, and the effect of illegitimacy upon it, I may mention the curious contradictions of these laws given by the statistics of Roumania: These show that the proportion of female to male births is 100 to 116, and, further, this proportion is not changed by illegitimacy.

[2] The difference in the weights of white male and female children is greater than it should be from these facts: first, a larger number of female children; second, in two cases of premature labor and in that of twins the children were females, and their weights being small, of course reduced the average.

Hospital records of the white children born there, that this weight was seven pounds four and eight-tenths of an ounce. The number from which this result was obtained was one thousand—five hundred males, and five hundred females. The average weight of the males was seven pounds and seven and nine-tenths of an ounce; while that of the females was seven pounds one ounce and seven-tenths.

The average duration of labor in the black women was very nearly fifteen hours, while in the white it was thirteen hours and twenty-five minutes—showing a difference in favor of the latter of more than an hour and a half, that is, labor is shorter in the white than in the black woman. This result is an unexpected one; nevertheless here again the number of cases is too small to justify a positive conclusion. The duration of labor in white primiparæ was fourteen hours nine minutes; in black, nearly eighteen hours; in white multiparæ, twelve hours forty-two minutes; in black, ten hours sixteen minutes. The duration of the third stage of labor was in the whites twenty-one minutes, and in the colored thirty-three minutes.

And here let me, for the time, at least, lay aside these statistics to consider the conduct of the third stage of labor. The subject invites consideration in this paper by the following facts: One of the colored women failing to expel the placenta within an hour after the birth of her child, the gentleman having charge of the case introduced his hand into the uterus and removed the afterbirth by piecemeal, or at least the greater portion of it. That patient had septicæmia, and infected each of her neighbors; the colored obstetric ward at this time was terribly crowded, the beds so close together that a patient could almost roll from her own bed into the next one.

Shortly after this I was called to a woman in one of the white obstetric wards, who had been delivered of her child three hours before, but the placenta was retained. The patient's pulse was good; there was no hemorrhage, nothing but the simple fact of delay in the third stage of labor. A little friction of the uterus, and compression of its fundus through the abdominal wall, caused the expulsion of the placenta in a few minutes. There was no fragment of the after-birth or of the membranes retained; the genital organs of the patient were not touched either by the *interne* or by myself in this delivery, nevertheless she had septicæmia. Finally, a third patient had the placenta retained for nearly five hours, and then it was expelled. She had septicæmia. These three patients recovered.

In studying the phenomena of placental delivery we find there are three stages, viz.: First, the separation of the placenta from the uterus; second, its extrusion from the uterine cavity after its conversion into a foreign body by its detachment; and, third, its expulsion from the vagina. Delay may occur in any one of these stages, that in the last, of course, being the most easily remedied. The separation of the placenta from the uterus is made by uterine retraction, and probably instead of being marginal in some cases, central in others, is usually general.

A practical question is here presented: Is this separation facilitated by ligating the placental end of the cord; in other words, ought the obstetrician to use two ligatures, or one? The advocates of two ligatures claim that in this case the placenta, being larger, fuller, firmer, cannot so well follow the retraction of the uterus as it can if thin and flexible from the loss of blood, and, therefore, in the former case is more certainly and completely detached. This is doubted by some, denied by others; nevertheless it seems rational. But admitting its truth, it is certain that if a single ligature be used the placenta is smaller, and hence can pass through a smaller uterine orifice; this practice, no matter what its effect upon the first, facilitates the second stage of placental delivery.

After uterine retraction has separated the placenta, uterine contractions expel it into the vagina, while the abdominal muscles, aided, it may be, in some slight measure by the contractions of the vagina, cause its final expulsion.

In the spontaneous discharge of the placenta from the uterus, it does not seem yet settled whether the placenta usually presents the fœtal surface or the margin at the os uteri. The doctrine of Matthews Duncan has probably, for the last few years, been most generally adopted by British and American obstetricians; my own belief is that it is correct—at least in some thirty cases of delivery, taking the method advised by Mr. Duncan to test the presentation, I found in the majority that the placenta descended through the os with its margin presenting. French obstetricians have not accepted Duncan's views; and, indeed, the recent observations of Pinard and others seem to prove that the placenta usually presents by its fœtal surface.

Now a practical lesson from this study of the mechanism of placental delivery is, that adopting the view of Duncan, traction upon the cord—a traction which, of course, is never to be made when the placenta is still attached to the uterus—is mischievous, for it interferes with the normal presentation; but if the normal presentation be that of the fœtal surface, such traction facilitates the second stage of delivery.

The time required for the spontaneous delivery of the placenta, as observed by Kabierski in one hundred cases in the Strasburg Maternity, varied from thirty minutes to twelve hours, as is shown by the following table:

24 times,	30 minutes.
20 times,	1 hour.
25 times,	2 hours.
11 times,	3 hours.
9 times,	4 hours.
5 times,	5 hours.
3 times,	6 hours.
2 times,	8 hours.
1 time,	12 hours.

Few practitioners are willing to trust nature this far, but guard against delay in the delivery of the placenta by following the uterus down with the hand upon the patient's abdomen, according to the expression and the method of the Dublin school, as the fœtus is expelled, thus keeping the hand upon the uterus at least as a sentinel to warn of uterine relaxation, and better still, as a stimulus to, and a reinforcement of, uterine retraction. A general observance of this practice reduces to a minimum cases of post-partum hemorrhage, of delay in the discharge of the placenta, and of hour-glass contraction.

And now, coming to the practical point of more direct interference with the third stage of labor, what circumstances demand it, and how is it to be made?

I believe the teaching of the Philadelphia school has been favorable to early interference—at least such delay as shown by the Strasburg statistics would not have been allowed by her great teachers. Dr. Hodge advised moderate traction upon the cord at the end of half an hour, or of an hour; and Dr. Meigs stated that he never waited for the spontaneous extrusion of the placenta more than an hour and a half, for he always supposed that if it would not take place in one hour, there was little prospect for its taking place in twenty-four hours. Now, with all reverence for the names of these great men, and with, I trust, due personal humility, it seems to me their teaching was wrong. Even moderate traction upon the cord, if the placenta be attached, is liable to do harm, and traction is not necessary to find out whether it is detached. The statistics quoted prove that one cannot make a time-table for nature in regard to placental delivery—she may effect that delivery long after Dr. Meigs's hour has passed.

As long as the placenta is wholly attached, hemorrhage is impossible; the placenta is still a living structure, and one with the uterus; to tear it loose, to detach it directly from the uterus, opens the way for perilous hemorrhage. Not only this, but such artificial detachment is usually incomplete, is liable to injure the uterine tissue, and the operator's hand may be the bearer of septic germs, or these may pass in with the air admitted during the manipulation, and find a congenial soil for their development in fragments of placenta, or blood-clots that are retained in the uterus. Therefore, unless hemorrhage demands immediate interference, the obstetrician refrains from passing his hand into the uterine cavity for the removal of an attached placenta; a completely adherent placenta is not so dangerous as the intrauterine use of the hand for its detachment. I believe, then, that armed expectation is wise in the latter case, only endeavoring, by suitable compression of the uterus with the hand acting through the abdominal wall, to determine or assist that retraction of the organ which is nature's method of separating the placenta. After the detachment of the placenta—a fact which is best learned by feeling a part of the organ with the finger passed into the mouth of the womb—we may, by friction and compression of the uterus, if needed, evoke uterine contractions which will cause its expulsion. Those who believe that the placenta presents its fœtal surface at the os uteri, urge the value of moderate and continuous traction upon the cord, thus assisting the moulding of the mass to the orifice through which it is to come. This conservative view as to the management of so-called retained placenta has been strongly presented by Siredey in his recent work upon puerperal diseases. The common expression, retention of the placenta, means very different conditions, each requiring its appropriate treatment.

Passing now to another topic, the relation of acute infectious diseases to the pregnant, or to the puerperal state, the history of the three months furnishes two cases of measles in pregnancy, and one of scarlet fever in puerperality. A report of the latter will appear in the next number of the *American Journal of the Medical Sciences*, and, therefore, is not presented here. In both the cases of measles the eruption did not appear until after labor, but in each the interval was so short that the disease was present in pregnancy. In one case the disease had no evident effect upon pregnancy, and the puerperal period was normal. But in the other I believe premature labor was caused by the disease, for though no accurate or definite information could be had from the mother as to when the pregnancy began—she was half idiotic—the child was small, feeble, and imperfectly developed. Abortion or premature labor is the result in the majority of cases when measles occur in pregnancy. The second patient had septicæmia, but even with this complication, and though quite ill, made a perfect recovery.

Puerperal temperatures is a subject of importance to which brief reference will now be made. I have here a temperature chart made by Drs. Phillips and Randall, from the charts of twelve women in whom puerperal convalescence was undisturbed; the chart includes eight days of the puerperal period. The highest temperature was on the fifth day, and then it was only 98⅘°.

Temperature record from two daily averages of twelve cases of normal recovery from labor. The first temperature is that of a woman delivered within the preceding twenty-four hours:

Morning,	98.4	98.4	98.2	98.2	98.2	98.4	98.0	98.2
Evening,	98.8	98.8	98.8	98.4	98.9	98.8	98.4	98.4

There were opportunities for observing the influence of apparently trifling causes in producing marked elevations of temperature. Thus one patient, whose condition was normal, insisted upon getting up the fifth day and dressing herself; she did so notwithstanding the remonstrance of the nurse, and her temperature rose to a little above 100°. Either from feeling badly, or possibly from the moral influence of the thermometer, she was willing to return to her bed. Another patient, doing well apparently, save that her temperature was 100°, got up the fourth day; her temperature rose to 103°; she returned to bed; her temperature in a few hours was only 100°, and in two days was normal. In another case an irritant cathartic, or that which proved to be such, the bitartrate of potassium, was given the fifth day, and for a short time the patient's temperature was nearly 105°, but the next day it was normal. On the other hand, the gravity of a case may be much greater than the temperature indicates. Thus in a patient with fatal septicæmia the temperature during the first five days only once rose as high as 101°—a part of the time was only 99°—on the sixth day rose to 102⅘°, on the seventh fell to 101°, and then on the morning of the eighth was 103⅗°; she died that day. In the abstract of a paper by Dr. Angus Macdonald (*British Medical Journal*, May 10), the statement is made that in some of the worst and most rapidly fatal cases of septicæmia, the temperature never rose over 101°, if so high. The explanation given was that the vital centres were attacked with such a quantity of the poison that death occurred before the tissue-changes ending in heat took place. Dr. Macdonald further referred to the important difference in the course of temperature in lymphatic and in phlebitic septicæmia; there being in the former a single rigor with sudden and continuous high temperature, and in the latter a series of successive rigors, followed by corresponding depressions. Siredey

has previously remarked that a temperature chart of a patient having puerperal septicæmia, will readily show whether the disease is the lymphatic or the phlebitic form. When Osiander, at the beginning of the present century, and others since him, described remittent puerperal fever, doubtless they had under observation cases of phlebitic septicæmia. I am sure these sudden and marked declines of temperature have led practitioners into false diagnoses, especially since attention was redirected by two distinguished American physicians to the occurrence of malarial fever in childbed; we would much rather believe a patient had this disorder than septicæmia, and such desire may assist the diagnostic error, an error I know that I have committed, and I have more than once witnessed its commission.

The occurrence of a chill at the onset of septicæmia is by no means a constant phenomenon. While Dr. Macdonald refers to a chill marking the advent of lymphangitis, Siredey regards it as always present in phlebitis, usually but not invariable in lymphangitis; it is multiple in the former, single in the latter. The cases observed at the hospital show that a chill was not constant in septicæmia, even in a fatal form of the disease. While we may in some cases, by the great variations in temperature, be able to diagnose between septicæmic phlebitis and lymphangitis, there are decided oscillations in temperature observed in the latter, though much less than in the former; and beside, some cases present the combined forms, lymphatics and veins alike affected.

The cases of septicæmia were too few, and the discrimination between lymphangitis and phlebitis not always made, to permit me to give a positive opinion; nevertheless, it seems to me probable that in lymphangitis the oscillations of temperature are always such that the thermometer marks a higher degree in the evening; while in phlebitis, the highest temperature occurs quite as often in the morning as in the evening.

Tarnier remarks that momentary elevations of temperature do not generally involve an unfavorable prognosis; but when they are progressive and continuous, especially when the thermometer placed in the axilla goes above $100\frac{4}{10}°$, some complication is to be feared. One of the subjects delivered at the hospital had a slightly subnormal temperature. She was a girl, eighteen years of age, who, three hours after a normal labor, had a temperature of 99°; this fell, so that on the third day it was only 98°, and so continued for a week. During a part of this time her pulse was 56, and even only 48.

The presence of albumen in the urine of the pregnant woman has often, even generally, engaged the attention of obstetricians; but comparatively little concern is usually shown as to its presence during labor, or in the puerperal state. Possibly, it may be quite as important to examine the urine of the lying-in as of the pregnant woman, especially if she has had even slight septicæmia. But first, how frequent is albuminuria in pregnancy? In seventy-two pregnant women albuminuria was found in five. It will be observed that this proportion is very much less than that given by Charpentier,[1] quoting Dumas, who, combining the statistics of several observers, makes the proportion one to five or six. It seems to me, both from hospital statistics and from observations in private practice, this proportion exaggerates the frequency of the accident.

By the albuminuria of labor is understood not only the disorder as occurring during labor, but also that of the two or three days immediately preceding. This is very much more frequent than the albuminuria of pregnancy, but the cases examined with reference to this point were too few to determine the proportion. Seven of the seventy-two women had albuminuria after labor; I think the number was much greater, but some of the women suffering with septicæmia did not have the urine examined until after convalescence, and the results of the examinations made in others were not properly kept, or at least were not placed in my hands. In three of the seven mentioned the albuminuria was slight and transient. In four women convalescing from septicæmia, the urine was found to be albuminous one month after delivery. Two had pus, blood, and hyaline casts in the urine; in a third, no pus, but blood and casts were present in the urine; as to the urine of the fourth, the microscopic appearances were not noted. In regard to two of these patients, I know that the catheter was first used after their being brought from the "fever" to the "convalescent ward," and, therefore, the explanation which Olshausen has suggested of the renal disorder fails in these cases—catheterism had nothing to do with its causation. In explanation of these cases, it is probably better to accept the teaching of Siredey, who regards puerperal nephritis as a constant complication of uterine lymphangitis or phlebitis.

Women may apparently, but not really, recover after pregnancy and labor; especially if there has been septicæmia, is there a liability of renal disorder becoming chronic, and it is only by actual examination of the urine that the integrity of the kidneys can be determined.

Mauriceau compares the pregnant woman just before labor to a ship that has been nine months tossing upon a rough sea, and urges the importance of not letting the ship sink as she enters the port of childbed. It is not less the duty of the obstetrician to know that the ship has not suffered such damage on the ocean or in the port, that she is unfit, without important repairs, to run the risk of another voyage.

Sugar in the urine of pregnant and of nursing women was first shown to occur by Blot in 1856. Differences of opinion hold as to the constancy of its presence in the conditions stated, as to its source and as to its character. Macdonald found it in each of thirty-five cases whose urine was examined, and, therefore, regards it as present in all cases at some time or other of the puerperium. But neither Kleinwächter nor Spiegelberg refers to it as always present. In the examinations made daily of the urine of fifty women at the hospital (these examinations began a few days before and continued seven days after labor), four women had sugar in the urine before labor, and six after labor, one of the six being also one of the four. In this woman the sugar was constantly and largely present up to eight weeks after delivery; she had remarkably well-developed mammary glands, and a most abundant secretion of milk. In this case Blot's suggested test for a good

[1] Traité des Accouchements.

nurse—to wit, the quantity of sugar contained in the urine—would have proved true, so far as abundance of milk was concerned.

It has been shown that abrupt suppression of nursing causes the appearance of sugar in the urine; thus it is commonly observed in mammary abscess.

The fact that removal of the mammary glands in an inferior animal recently delivered, causes disappearance of sugar from the urine, proves that it is incorrect to call the cases in which sugar is found in the urine in pregnancy or childbed, cases of glycosuria, but rather of lactosuria, unless we attach only the literal meaning to the first word in the compound glycosuria. Spiegelberg refers to the condition as an absorption diabetes; and this seems the opinion of most authorities. Tarnier, however, regards as very plausible the hypothesis that the sugar eliminated by the kidneys was sugar made, very probably, by the liver in view of the lacteal secretion, and which was not utilized in consequence of the momentary suppression of this function; further, he thinks new researches necessary, in addition to those of Hofmeister and others, to determine the question as to whether this sugar is glucose or lactose.

Whenever there is an exact correspondence between the milk supply and the demand, the former not being in excess of the latter, it is probable sugar will not be found in the urine; I think, therefore, that the experience of Macdonald—showing saccharine urine in all cases of lying-in women—is not the law.

An interesting case of secondary puerperal hemorrhage occurred—interesting as to its etiology, and instructive as to the means by which it was finally arrested.

The following is the history as given by Dr. Voorhees, the *interne* who had charge of the patient:

A. A., German, single, primipara; varicose condition of veins of lower limbs, this condition disappearing after labor. Labor at full term, March 5, 1884, lasting a little over twelve hours. Her condition was perfectly satisfactory up to the evening of the eleventh day after confinement; on that day she was transferred to the convalescent ward, and then saw the out-door agent as to keeping the father of her child in prison for refusing support. She was greatly distressed by this interview, and at 4.30 the next morning hemorrhage began. Digital examination showed that the blood came from the uterus; the os was high up, flabby, and full of clots; the uterus was as large as if delivery had just occurred, and was soft and relaxed. Ergot was given; the child applied to the breast; the uterus was emptied of its clots, and friction used to stimulate contraction, but the bleeding still continued. Ice was then used to the abdomen, and in the vagina; the bleeding was not stopped. Hot water was then freely thrown into the uterus and the result was prompt and satisfactory. The patient made a good recovery. Although the uterine discharges were carefully examined, at no time was there any organized material found, nothing in the least indicating that this hemorrhage was caused, for example, by the retention of a placental fragment.

Those who have read Dr. Fordyce Barker's admirable lectures upon puerperal diseases, will remember the graphic description of a case of secondary hemorrhage the second day of lying-in, caused by an emotional cause, and in what perilous condition the poor woman was for some days. So too in the hospital case we have an example of hemorrhage from a psychical case. Believe or doubt as we may, say what we will, there are at times in medical practice just such sudden, startling, and strong proclamations of something more than flesh and blood in this human nature, telling us that the coarse material may be prostrated through the finer spiritual, the psychical assert its power over the physical.

Further, as to this case, the great value of hot-water injections for the arrest of uterine hemorrhage never had a more striking illustration.

The final subject presented to you is that of uterine rupture. In reflecting upon the history of my three months' service, no event occurred in my duties to these unfortunate women—women often worthy of the profoundest pity as the victims of misfortune, and of man's perfidy—which causes me greater sorrow in silence or in recital than a case in which the uterus was ruptured in consequence of a shoulder presentation, a case which ended in death the eighth day after delivery. Yet I would fail in duty to my profession that has been so good, so generous to me, if I did not make the case fully known. The patient was a well-formed healthy multipara; she had been in labor nearly twelve hours when I first saw her, the left shoulder presenting. Ether was immediately given until she was thoroughly under its anæsthetic effect; and then, without violence, nay, with great ease, I passed two fingers behind the right knee, brought the foot down, and turning and delivery were effected in a few minutes; the placenta followed almost immediately; the child, quite a large one, was dead. The patient came out from the anæsthesia satisfactorily; her pulse was good; there was no complaint, no shock, no great hemorrhage. Yet that woman had a ruptured womb, the tear beginning at the os uteri on the right side, involving the cervix and the lower part of the body of the uterus, this condition being made known by the post-mortem. If it be thought I ought to have known this accident at the time of delivery, I can only say that like ignorance happened to Dubois, to Hervieux, to Tarnier, and others—the first revelation of the uterine rent being made at the post-mortem; these silent tears of the womb are, as Hervieux has suggested, probably more frequent than generally thought. No, my self-reproach is not in this, but in not having made myself, or by another, an examination during pregnancy, so that the abnormal presentation could have been corrected, if not then, at least early in labor. But let this pass. The great practical lesson to be drawn from the accident is not only the importance of an early rectification of a malpresentation, but also an appreciation of the danger of rupture of the uterus, and how this accident occurs. A drawing which was shown gives the position occupied by the child, and also and especially gives the change in form and thickness of the two cavities of the uterus, which, as so admirably described by Bandl, are formed when nature is unable to overcome the obstacle to labor found in such case. The one cavity is formed by the body of the uterus, and its walls become thicker and stronger; the other, by the cervix, and its walls grow thinner—become indeed so attenuated and weak that a very slight additional strain causes a tear at some point; that strain may come from a uterine contraction, or solely from the introduction of the finger: and thus peril from action, peril from delay must be

before the obstetrician's mind when called to a case of neglected shoulder presentation.

Of course, had I seen this patient an hour or two earlier, the event might have been different. The pressure of the presenting part had been so severe that a slough of the vesico-vaginal wall occurred, and the patient, had she recovered, would have required an operation for the resulting urinary fistula; I have thought that possibly the uterine rent was in part the result of a slough also; but be this as it may, there was not the slightest indications given at the post-mortem that any hemorrhage into the abdominal cavity had taken place.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Special Meeting, June 6, 1884.

The Vice-President, Dr. B. F. Baer, in the Chair.

Dr. Goodell gave the following history of a

CASE OF HYSTERECTOMY.

The woman was unmarried, aged 47. Her monthly fluxes began to be free in 1867. A year ago they became so exhausting that she could not pursue her trade as a seamstress. On April 30th, she consulted Dr. Goodell, who found the whole abdomen filled with multiple fibroids. The cervix had disappeared and the os uteri lay so high up that it was not possible to introduce the sound. The operation was performed at the hospital of the University of Pennsylvania on May 22d. One outgrowth as large as the two fists contained a cavity filled with cheesy matter, and was so adherent to the abdominal wall and intestines as to need the knife for its release. It was possibly the right ovary, but he was by no means certain. Kœberlé's wire clamp was passed around what corresponded to the neck of the womb, but it was as large as his arm above the elbow. The woman's recovery thus far has been uninterrupted. The temperature reached 100° but once. The clamp fell off on the 16th day, leaving a very deep, funnel-shaped pit. He had intended to exhibit the specimen, but it was too bulky to carry, and also had become quite offensive. In this case, had he been able to reach the ovaries or to have discovered them, he would have removed them in preference to performing hysterectomy; but the firm adhesions prevented the rotation or the lifting up of the tumor, hence the ovaries were inaccessible. Sometimes even when the uterine fibroid can be lifted out of the wound and the ovaries reached, these organs are so imbedded in the fibroid, or so drawn out in ribbon-form on the surface of the tumor, as to make their complete removal impossible. When, however, the ovaries can be removed with safety the operation is a most promising one, as he could attest from several most successful cases.

Dr. W. T. Taylor reported the following case of

PARTIAL PLACENTA PRÆVIA.

Mrs. S., an English woman, aged 46 years, the mother of ten children, came to see him in December, 1883, in consequence of abdominal pains, headache, and vertigo, with a suppression of her menses, which she attributed to a "change of life," as she had been irregular for a year past. She also had numbness with tingling in the hands and feet, and had not been so affected in any former pregnancy. Consequently she would not believe in her condition until some weeks later, when she quickened. In the month of February last she had enlargement of the veins of the legs, with œdema of the feet and ankles, for which she took occasional doses of potassium bromide with a solution of cream of tartar (one ounce to the pint of water). By this treatment she was temporarily relieved.

On March 27th, she had abdominal pains and a profuse hemorrhage, which saturated her clothing and greatly alarmed her. On examination he found the os uteri high up and slightly open. Although the hemorrhage diminished, yet the pains would recur at intervals, and he fully expected labor would soon begin. Under the use of equal parts of wine of ergot and solution of sulphate of morphia, she began to get easier, and in a few days was out of bed and able to resume her household duties; feeling more comfortable, as the enlarged veins were smaller, her feet and ankles had diminished in size, and the headache gone entirely. I told her that nature had come to her relief and bled her without my ordering it.

Feeling satisfied that this was a case of placenta prævia, and that there was no immediate danger, I concluded the most prudent course was to let nature alone and wait until labor began. She had no more trouble until May 10th, when she passed a large clot of blood and complained of slight pains in the abdomen, these occurred occasionally for two days, when the membranes ruptured, and a sudden gush of water, followed by a flow of blood, indicated that labor had begun. On examination, I discovered within the os a spongy, ragged, bleeding mass of tissue, which was recognized as the placenta; with each pain the flow of blood increased as the cervix dilated. Sweeping my index finger around within the mouth of the womb, as far as I could reach, to detach the placenta from the uterine walls and assist the first stage of labor, I felt the fœtal head beyond.

To arrest the bleeding, which, if it continued, would exhaust the mother and destroy the child, I plugged the vagina completely with strips of old muslin, well saturated with lard, and waited patiently for the os to dilate and the head to advance, giving at the same time occasional doses of quinine and wine of ergot as a tonic and stimulant. In about an hour the advancing head had expelled a part of my tampon and on removing the remainder I found that the bleeding had ceased and the vertex was presenting in the left occipito-posterior position. Auscultation revealed a feeble fœtal circulation, but as the pelvis was roomy and my patient somewhat exhausted, I gave her freely of milk punch until her pulse became stronger, which it did in half an hour, when, as the head had ceased to advance, I applied the forceps and delivered her of a medium-sized girl, which in a few minutes began to cry with some vigor, contrary to my expectations, for I had told them it would probably be dead. Its vitality had been preserved by the adhering part of the placenta, which then came away quite easily. A teaspoonful of fluid extract of ergot contracted the womb firmly. My patient was weak for several days, but under the use of tonics with nourishing food, she soon recovered her usual strength.

Dr. A. H. Smith remarked that this case being partial and without profuse hemorrhage, could have been best carried through by rupturing the membranes and

bringing down the head, which would have stopped the hemorrhage as soon as it engaged in the superior strait. Dr. Smith asked the question: Under what circumstances are we warranted in interfering? If the hemorrhage is alarming and the patient exhausted, she is in a poor condition to bear interference, and, on the other hand, we have no right to interfere if there is no pain or hemorrhage. To interfere by manipulation is very dangerous, unless the uterine contractions are rapid and effective after labor once begins. The position of the child should be carefully and accurately determined by external manipulation before interference becomes necessary, so as to know where to seek the feet, if turning becomes imperative. When the placenta prævia is complete, dilatation of the os causes a terrific hemorrhage, the blood streams from the patient like water from a hydrant, or a small fire-plug, and death comes very quickly. Only perfect knowledge of the condition of things, and the position of the child will enable the physician to avert the doom. Now, as to the tampon. I would not use it. It hides the hemorrhage, which may be going on profusely behind it as was so vividly described by Dr. Goodell, in his paper on "Concealed Accidental Hemorrhage of the Gravid Uterus," in vol. 2 of the *American Journal of Obstetries*, in which he showed that the woman might bleed to death without one drop of blood escaping externally. The tampon conceals the hemorrhage without necessarily preventing it, and while it remains in place one hand of the physician should be constantly on the patient's pulse to note instantly any failure of the heart; while the other should be on her abdomen to note any changes in size of the uterus, or position of the fœtus. In Dr. Taylor's case the treatment was beyond criticism, because the result has been happy.

DR. GOODELL agreed with Dr. Smith that placenta prævia is the most formidable complication in obstetrics. No general rule can be made applicable to the treatment of all cases. In partial ones, the membranes should be ruptured and the head brought down. It must always be borne in mind that in these cases the implantation of the placenta has caused increased vascularity and thickness of the cervical walls; they are easily ruptured, and if torn bleed profusely. There is greater danger of septicæmia from absorption of decomposing lochial discharges when passing over this surface, if it is torn. He well remembered one case which he attended years ago in consultation with Dr. Augustin Fish, since deceased, in which, in consequence of what he now considers undue haste, lacerations of the cervix occurred and, although the labor terminated happily, septicæmia set in a few days later and resulted fatally. It would have been better in that case to tampon. When the placenta is not central there is very little danger—there is some. The tampon may be used, but the pulse must be constantly watched and frequent abdominal palpation should be made. He had been struck with the method practised by Dr. Ellwood Wilson more than twenty years ago. It consisted in gentle digital dilatation of the os; introducing first one finger then two, and so on; as soon as sufficient space was obtained he gave ergot, made podalic version and delivered. Very few practitioners advise that method. Dr. Goodell had not met with many cases, and the one spoken of above was the only fatal one. He has used Barnes's dilators, taxis, strength, and courage, and has tried to adapt his treatment to the indications of each particular case.

DR. W. H. PARISH thought the tampon was not used as frequently now as it was a few years ago, either in the form of Barnes's dilators, or the vaginal plugs. Under similar circumstances he would probably do as Dr. Taylor did. Partial placenta prævia is not very dangerous, but in complete the hemorrhage is excessive. In one case he had tamponed for several hours when, the os being dilated, he etherized and rapidly delivered a living child. The mother was in imminent danger of death from hemorrhage. The abdominal aorta was compressed, ice was used to the cervix, but without success. The hemorrhage was controlled by the application of a cloth wet with Monsel's solution to the denuded cervical and uterine surface.

DR. TAYLOR has used the tampon in several cases of partial placenta prævia and in numerous cases of abortion, and has never yet had bleeding to go on behind it. The line of treatment practised in this case has always proved satisfactory as regards results.

DR. GOODELL remarked that the womb at term was large, and concealed hemorrhage might be free enough to cause death, but there was no such danger in an abortion at two or three months.

DR. B. F. BAER exhibited a specimen of

SUBMUCOUS AND INTERSTITIAL UTERINE FIBROID,

and read the following report of the case: Mrs. G., æt. 51 years, married, four children. Her first child was born after she had reached her thirtieth year, and the last one when she was thirty-eight, thirteen years ago. Her labors were very severe. Several years ago she began to lose large quantities of blood with her catamenial periods and to suffer severely with labor-like pains. This continued with increasing quantity and severity until the cause was removed. Two years ago she had so great a flooding that it was thought for weeks that she would succumb. She gradually recovered from the immediate effects of the hemorrhage, but has been losing flesh and strength ever since. Moreover, as soon as she would recover a sufficient amount of strength to support it, a severe metrorrhagia would recur. Recently she had rarely been free from bleeding and a profuse nonfetid watery discharge.

At the request of my friend, Dr. Fred. C. Seiberling, the family physician, I met him at the home of the patient, at New Tripoli, Lehigh County, Penna. When I saw her for the first time, she had a sallow, jaundiced and anæmic looking surface, was somewhat emaciated, but did not have the characteristic cachectic appearance of carcinoma. Her pulse was 120, and not strong. As she was too weak and excited to permit of a thorough examination without it, ether was at once administered by Dr. J. W. Seiberling, when the following condition was revealed by physical exploration: The upper portion of the vagina was occupied and distended by the cervix uteri, which was stretched and expanded over a firm rounded mass which presented at the os; the latter was dilated to about the size of a silver dollar, and the body which presented resembled very much in size and shape the head of a seven months' fœtus. Bimanual examination showed the uterus to be as large as at the end of the sixth month of gestation and rather

symmetrically developed, but it was quite firm and resisting, if not hard. The sound could not be introduced for the following reason: On the right side the tumor was firmly attached to the cervical wall all the way to the external os, and on the left almost to the same extent, though here I was able to pass the sound and finger to the depth of about an inch. I confirmed Dr. Seiberling's diagnosis of submucous fibroid, and thought, from the size of the uterine globe as outlined by abdominal palpation, that the tumor had also a deep interstitial attachment or *nidus*. I advised an attempt at enucleation of the growth as the only means of saving the life of the patient, and, with the assistance of Drs. F. C. Seiberling and W. K. Kistler, I proceeded with the operation. I was at a loss at first to explain the close connection which the tumor had with the cervical walls, a connection so intimate that it seemed in part to grow from that organ, but the history of the growth of the tumor was against that idea; the patient had been under close observation at least four years, during most of which time the cervix was free from disease. There had been no evidence of abnormal growth in the cervix until six months before the date of operation; about that time the tumor was detected at the internal os. I thought that the close connection with the cervical wall might have been due to adhesive inflammation, and acting on that theory I began my operation by trying to separate the adhesions, but I soon found that I had made a mistake and that I was dissecting up the tissues of the cervical wall. I then concluded it must be the capsule of the tumor which had been stripped off by the growth as it was made to advance towards the external os by contractions of the uterus, and this view was confirmed; for when I had removed the tumor, the capsule hung as a curtain from the edge of the external os. After vainly endeavoring to deliver the tumor by traction, I cut directly into it with scissors, dividing the mass into two portions. I then introduced Thomas's spoon-saw into the cavity, and with it and my fingers I tore the growth from its nest in the fundus and sides of the uterus, removing it piecemeal. Very little hemorrhage occurred during the operation, which occupied fully an hour and a half. After trimming the ragged edges of the capsule from around the os, I injected the cavity with vinegar and packed it full of sponges saturated with the same excellent antiseptic and hæmostatic. A gr. ss morphia suppository was placed in the rectum, the patient removed to her bed and surrounded by bottles of hot water. She reacted nicely, and in the evening ten grains of quinine were given. On the next day the sponges were removed, the cavity irrigated with carbolized water and repacked as before. Under the care of Dr. Seiberling the patient has recovered without an untoward symptom. The tumor probably weighed three pounds.

STATE MEDICAL SOCIETY OF WISCONSIN.

Thirty-eighth Annual Session, held at Milwaukee, June 3, 4, and 5, 1884.

(Specially reported for THE MEDICAL NEWS.)

THE State Medical Society of Wisconsin, held its Thirty-eighth annual session in Milwaukee, June 3 to 5 ultimo, the attendance being good and the spirit of the meeting excellent.

One evening was wholly devoted to clinical work, with exhibition of cases, specimens, etc., and demonstrations of work, proving one of the most profitable features of the session.

Several of the papers which were presented were thoroughly discussed, among them one by Dr. Brett on the *Treatment of Fractures of the Lower Extremity*, and another by Dr. Ladd on *Conservative Treatment of Injuries of the Hand*. An active and profitable discussion was also aroused by the *Report on Pathology*, in which the writer, Dr. Steele, took the ground that there is not yet sufficient reason for the conclusion that the bacillus is the sole and only cause of tuberculosis, holding that long-continued clinical observation by many careful and accurate men, has shown that there may be other causes efficient to produce tuberculous disease, citing especially those occupations in which dust is constantly inhaled. While conceding to Koch profound ability and genius, and acknowledging that the tubercle-bacilli will produce tuberculosis, he believed that it has not yet been demonstrated satisfactorily that tuberculosis cannot be produced by other causes and contended that the clinical evidence that it may be so caused is too strong to be overthrown without further evidence and experiment.

These views were vigorously opposed by Dr. Senn, who held that the causal connection of the bacillus with tuberculosis was as thoroughly proved as any fact in clinical medicine can be, and that tuberculosis wherever found is invariably produced by specific germs—that the presence of this bacillus is not only the sole cause, but also the most reliable diagnostic criterion.

Dr. Epley introduced a resolution concerning the relations of medical men to courts of justice as expert witnesses, and a committee was appointed to consider this question and to report what changes in the law are needful to secure reasonable compensation for witnesses summoned to give testimony solely as experts.

Papers were read on *Acute Dysentery*, *Uterine Fibroids*, *Inversion of the Uterus*, *Anthrax*, *Alcohol*, *New Remedies*, *Lithotrity*, etc.

Twenty-two new members were admitted to the Society. Its next meeting will be held in Milwaukee.

THE OFFICERS FOR THE ENSUING YEAR:

President.—Dr. E. W. Bartlett, of Milwaukee.

First Vice-President.—Dr. S. L. Marston, of Fond du Lac.

Second Vice-President.—Dr. G. M. Steele, of Oshkosh.

Permanent Secretary and Treasurer.—Dr. J. T. Reeve, of Appleton.

Censors.—Drs. J. K. Bartlett, N. Senn, Wm. Thorndike.

NEWS ITEMS.

WASHINGTON.

(*From our Special Correspondent.*)

RECENT LEGISLATION.—The following bills affecting the public health have become laws: To establish a bureau of animal industry; prevent the exportation of diseased cattle; and provide for the suppression and extirpation of pleuro-pneumonia and other contagious diseases among domestic animals. The following were

incorporated in the Sundry Civil Apppropriations Bill: To authorize the President, in case of threatened or actual epidemics, to use the unexpended balance of appropriation made by the Act of August 7, 1882, and March 3, 1883, in aid of State and local boards of health, or otherwise, in his discretion, in preventing and suppressing the spread of the same, and maintaining quarantines at points of danger; to prevent the admission to the Government Hospital for the Insane of inmates of the Soldiers' Home who are now, or may hereafter become insane; to provide for the appointment of a scientific commission, which may, in the name of the United States Government, conduct a National Conference of Electricians in Philadelphia in the autumn of 1884; to authorize the National Academy of Sciences to receive and hold trust funds for the promotion of science and for other purposes.

The following proposed legislation failed: To provide for the inspection of meats intended for exportation, and to prohibit the importation of adulterated articles of food and drink, and to authorize the President to prohibit importation in certain cases; House bill proposing that the use of distilled spirits be restricted to scientific, mechanical, and medicinal purposes; House bill to purchase the Seaman's Retreat Hospital and grounds for marine-hospital purposes; House bill to reënact the Quarantine Act of June, 1879 (which expired by limitation), giving the National Board of Health certain powers and assigning certain duties to it—reported adversely. A provision in the Sundry Civil Bill, with Senate amendments, appropriating $25,000 for the National Board of Health, and to carry on certain investigations, was stricken out in Conference Committee.

NEW ORLEANS.

(From our Special Correspondent.)

THE NEW ORLEANS MEDICAL AND SURGICAL JOURNAL has been reorganized, so far as the editorial department is concerned. Three of the old corps retire, and the remaining two unite with eight others to form the New Orleans Medical Publishing Association. Those who have undertaken this work are active and well-informed young physicians, who promise a good journal.

THE JOINT CONFERENCE OF THE BOARDS OF HEALTH OF THE GULF STATES AND OF TENNESSEE was held here some two weeks ago. This was a plan of the new President of the New Orleans Board to establish harmony and concert of action between the various Boards of the Mississippi Valley and the cotton States. The order of business included discussion of: 1. Maritime quarantine; 2. Coöperation between States; 3. Quarantine and commerce; 4. Non-intercourse; 5. Period of detention; 6. Treatment of infected and non-infected vessels; 7. Disinfection; 8. Legislation; and 9. Inter-State and local quarantine. The session lasted three days, and the discussions apparently resulted in harmony. Under the Louisiana law, *detention* is the declared principle of quarantine as at present administered. The limit is fixed at forty days, and our new president detains all tabooed vessels for this period. His object in thus enforcing the law is to encourage legislation changing the law from detention merely to scientific disinfection.

In this connection we quote from his address to the Board, April 24, 1884, "There are those, and I announce myself as of their number, who hold that it is possible, and experience abundantly justifies the declaration, that yellow fever may be called into activity in New Orleans without recent importation, or importation at all, as far as we are able to decide." If it is endemic, of course all quarantine is unnecessary. But I believe Dr. Holt thinks yellow fever may also be imported. Consequently, his forty days' term is to starve out this invasion wing of the enemy's forces and prevent their combination with indigenous allies. Quite a number of competent medical observers believe with Dr. Holt that yellow fever may be of *de novo* origin in New Orleans. This belief rests upon the unassailable fact that many outbreaks have occurred in regard to which importation could not be established. These circumstances so often attend outbreaks of all infectious maladies as to suggest as the most easy explanation the endemic origin as characteristic of this class of disease.

THE TULANE BILL, merging the various departments of the University of Louisiana, including the medical department, into an institution to be called the Tulane University, has almost passed the Legislature. It will still have to be voted on by the people as an amendment to the Constitution, but its immediate effects will be to put the Tulane administrators in charge of the various departments. Changes will doubtless be made in the courses of study as well as the methods of teaching, which, with the munificent endowment, will place the University of Louisiana in the front rank of institutions of learning which are well endowed and well systematized.

THE TEMPERATURE has been peculiarly low in New Orleans, both absolutely and especially as compared with the other cities and towns of this district. No good explanation of this fact has been given, except that the city is so thoroughly surrounded by water, including the overflowed district just across the river. Malarial fevers are unusually few in number, but smallpox still claims about ten a week. Alarmists recall the fact that 1878 was a counterpart of this year in so far as the temperature and rainfall (the latter excessive now) are concerned, and, therefore, yellow fever is unavoidable. Intestinal disorders are everywhere rife, and many children are dying with cholera infantum. The city is not very cleanly, and these daily rains prevent the sun from drying the filthy gutters, masses of garbage, and unclean yards of the lower classes. This is a matter of much importance in sanitation in this city. Remember, in the first place, the river is higher than the city, and, therefore, we must drain from the river to the lake; and, in the second place, the fall from the river to the lake, a distance of from five to seven miles, is only ten or twelve feet. Underground sewers are inadmissible; we, therefore, drain by open gutters. Sewer gas is thus unknown to us, but it is impossible to flush all the gutters, and those not flushed become long lines of stagnant putridity.

THE MORTALITY figures for the week ending June 28th was as follows: white males, 63; white females, 47; colored males, 42; colored females, 38; total, 190. This is an annual death-rate of over forty per thousand of population.

CHOLERA.—A dispatch from Toulon dated July 7th, states there were nine deaths from cholera during the past twenty-four hours and that the cemeteries are kept open at night to allow speedy burials. A Marseilles dispatch of same date gives sixteen deaths from cholera during twenty-four hours last past, and that twenty cases had been taken to the hospital. The Consul at Calcutta reports one hundred and fifteen deaths from cholera at that place during the two weeks ending May 24th.

Mail matter from France is to be overhauled in the British post-offices and stowed in a separate part of mail ships bound to the United States: whether this separation is sufficient guaranty to prevent the introduction of cholera is to be left to the health officers of United States ports, who may require its disinfection if they see proper to do so.

REPORTED CHOLERA IN NEW YORK.—A reported case of "true" Asiatic cholera was heralded by one of the morning papers of Washington on Monday last. It turned out to be a case of "stomach-ache," with cramps, and the patient was convalescent the next day.

YELLOW FEVER.—One death from yellow fever is reported at Pernambuco by the consul at that place, for the week ending June 7th, and three deaths at Santiago de Cuba for the same period.

Thirteen deaths from this disease are reported by the consul at Rio for the two weeks ending May 31st.

Reports from Ship Island, Sapelo, and Cape Charles quarantine stations indicate a healthy condition of affairs at those stations, with no yellow fever cases in hospital.

THE JUNIATA VALLEY MEDICAL ASSOCIATION will hold its annual reunion at Cresson, on the Allegheny Mountains, on Tuesday, July 15, 1884. The Association cordially invites all members of County Societies to participate in its doings.

A FAREWELL BANQUET was given to Drs. S. C. Busey, D. W. Prentiss, W. W. Johnston, and J. S. Billings, at the Arlington Hotel, Washington, on June 28, by the Washington Obstetrical and Gynecological Society, on the occasion of the departure of these gentlemen for Europe to attend the Copenhagen International Medical Congress.

M. PASTEUR has received a gold medal, from the Central Society for the Improvement of the Canine Race, for his researches in hydrophobia.

AN EXCURSION TO THE LEPER DISTRICT.—After the session of the International Congress is over, on August 17, it is proposed to organize an excursion to Bergen and Norway, where leprosy is prevalent. The excursion will last about fifteen days, and will be directed by Dr. Armäner Hansen. Those desiring to participate should write to Dr. Haslund, Chairman of the Committee on Dermatology, at Copenhagen, before the middle of July.

SEVENTH RIBERI PRIZE.—The subject for the seventh Riberi Prize, of 20,000 lire, is: "Embryological Researches, particularly as regards the Anatomy, Physiology, and Pathology of Man." Manuscripts must be written in Italian, French, or Latin, and must be presented by December 31, 1886.

OBITUARY RECORD.—ALEXANDER TWEEDIE, M.D., F.R.S., died on May 30th, at the age of ninety. Dr. Tweedie was born in Edinburgh in 1794. In 1809 he commenced his medical studies at the University of Edinburgh, and in 1815 took his degree of M.D. In 1817 he became a member of the Edinburgh College of Surgery, and was then elected one of the two house surgeons to the Edinburgh Royal Infirmary, Robert Liston being the other. In 1820 he moved to London, and in 1822 was admitted a Licentiate of the College of Physicians. He became a Fellow of the College in 1833, and was Lumleian Lecturer in 1858 and 1859. In 1824 he was appointed Physician to the London Fever Hospital, which position he filled for thirty-eight years.

NOTES AND QUERIES.

PEPTONIZED MILK IN SUMMER DIARRHŒA OF INFANTS.

To the Editor of THE MEDICAL NEWS.

SIR: The report of my paper on the "Summer Diarrhœa of Infants," published in the NEWS of to-day, is full and more accurate than I expected; since it was read rapidly and with many omissions through want of time, but there is one error, which, as it relates to the important matter of feeding infants, I wish to correct. The report reads: "Of this peptonized cow's milk, one part to three parts of water should be used for a child of one month," etc.

The dilution here recommended is for milk not peptonized. Peptonized milk does not in my opinion require any further dilution than that employed in the peptonizing process. In the institutions with which I am connected, and in my private practice, I have not recommended any additional dilution even for the youngest infant.

Yours truly,

J. LEWIS SMITH, M.D.

NEW YORK, July 5, 1884.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 1 TO JULY 7, 1884.

PROMOTIONS TO DATE FROM JULY 2, 1884.

GLOVER PERIN, to be Assistant Surgeon-General, with rank of Colonel.

ANDREW K. SMITH, to be Surgeon, with rank of Lieutenant-Colonel.

PASSMORE MIDDLETON, to be Surgeon, with rank of Major.

MIDDLETON, J. V. D., *Major and Surgeon.*—Ordered to relieve Surgeon B. E. Fryer from duty as Post Surgeon, Fort Leavenworth, Kansas, on or before July 1st.—*Par. 5, S. O. 133, Headquarters Department of Missouri,* June 28, 1884.

GIRARD, J. B., *Captain and Assistant Surgeon.*—Ordered to relieve Surgeon W. E. Waters from duty as Post Surgeon Plattsburg Barracks, Plattsburg, N. Y. SURGEON WATERS, upon being relieved, is directed to return to his proper station (Madison Barracks, N. Y.).—*Par. 3, S. O. 131, Headquarters Department of the East,* June 30, 1884.

BENHAM, R. B., *First Lieutenant and Assistant Surgeon.*—From Department of Dakota to Department of Texas.

GORGAS, WM. C., *First Lieutenant and Assistant Surgeon.*—From Department of Texas to Department of Dakota.—*Par. 8, S. O. 150, A. G. O.,* June 28, 1884.

BIRMINGNAM, H. P., *First Lieutenant and Assistant Surgeon.*—From Fort Bayard, New Mexico, to Fort Bliss, Texas.—*Par. 3, S. O. 137, Headquarters Department of Missouri,* July 3, 1884.

WALES, PHILIP G., *First Lieutenant and Assistant Surgeon.*—From Old Fort Colville, Washington Territory, to Fort Cœur d'Alene, Idaho.—*Par. 3, S. O. 89, Headquarters Department of Columbia,* June 23, 1884.

SYMPATHETIC OPHTHALMIA.

An Abstract of a Clinical Lecture Delivered at the Jefferson Medical College Hospital.

BY WILLIAM THOMSON, M.D.,

OPHTHALMIC SURGEON TO THE HOSPITAL.

THE two cases now before you we wish you to study carefully, and trust that the picture presented by that small, anæmic boy, with his downcast face, peculiar, haggard expression, and closed eyelids will impress itself so indelibly upon your minds that it will not readily be effaced. That, Gentlemen, is one of the most typical cases of sympathetic ophthalmia we can bring before you.

The history of the case is, briefly, as follows: About December 15, 1883, the lad, while cutting a cord with a sharp-pointed knife, accidentally punctured the left eye. The wound, as you see, is in the ciliary region, near the cornea, in the inner and lower quadrant, on the nasal side of the eyeball, at least five millimetres in length. Very little hemorrhage followed the injury, neither was there any pain at the time. The day following, vision became hazy and sight began to disappear; traumatic cataract developed; serous iritis followed, occluding the pupil. There can be no doubt that the inner coats of the eye, especially the choroid, by its continuity of tissue, became inflamed and their structures destroyed, or at least so invaded by exudative products—leucocytes, possibly micrococci—as to injure their normal structures. The treatment instituted was bandages and cold applications.

Inasmuch as there was not much pain in the eye—although blind—the boy was permitted to run about, and on January 2d was sent to school. Two days after this, without any premonition of trouble in the right eye—the uninjured one—the lad suddenly found objects enveloped in a haze; this condition grew rapidly worse, and in two weeks only qualitative perception of light remained, *i. e.*, could only tell the difference between day and night. In examining the left eye, you see the cicatrix of the wound, the grayish-green color of the iris—balloon-shaped, the pupillary space filled by a mass of lymph, the diffused pink color of the sclerotic—due to congestion of the small arteries, the photophobia, and some lachrymation.

The same clinical picture is seen in the right eye—possibly a greater deposit of lymph in the anterior chamber, and a darker tint to the sclerotic vessels.

Relative to the treatment in this case, nothing can be done to restore vision; the lad is hopelessly blind. We can only alleviate symptoms. For the irritation of the eyelids, a mild astringent lotion, such as acid. borac., grs. iij, to aq. camph. and aq. destil. āā f℥ss. If we wish to use atropiæ sulph., to relieve the iritic pain, we can combine atropiæ sulph., gr. j, with ung. boroglyceridi, ℥iij. Internally, tonics and good food, to keep up the muscular tonus of the general system. In the earlier inflammatory stage, probably calomel, grs. j to ij, guarded by opium, forced to salivation, might have modified the virulence of the disease. The proper course to have pursued should have been the enucleation of the injured eye, as a prophylaxis.

This man was injured April 4th, by a chip of steel off a chisel—seventeen days ago. The wound is in the ciliary region, on the nasal side of the eyeball, just below the tendinous attachment of the internal rectus muscle. Already do we find a slightly hazy cornea, circumscribed ciliary injection, a wound six millimetres in length, in which the iris is incarcerated, giving the pupil an ovoid shape, notwithstanding the fact of its being under the influence of a mydriatic. An ophthalmoscopic examination revealed a delicate haze of the cornea, lens clear, but vitreous turbid, not allowing the details of the fundus to be defined; but down and in toward the nasal side of the fundus, a few lines beyond a point corresponding to the lower lip of the wound, we obtained a whitish reflex—no doubt the foreign body covered with exudative material. No untoward symptoms have become manifest other than slight twitchings of pain through the eyeball, which are at times reflected to the infraorbital nerve. Vision almost *nil*. No photophobia. The right eye is normal in every respect.

As regards the treatment, what shall be done? When we recall the lamentable condition of the small lad, we know of only one remedy that will protect the quiet eye, and that is, enucleation of the injured one. Before the stage of irritation has developed we can enucleate with safety. If we were to wait till vision became blurred, or serous iritis developed, then surgical interference would not only be too late, but might aggravate the inflammatory condition of the sympathizing eye; or, again, as has often been found, the primarily injured eye might remain the better of the two.

We will not detain you by reviewing the different theories of sympathetic ophthalmia—as to whether the probable route to the sympathizing eye is by the optic nerve, or through the ciliary nerves, or by way of the perineural lymph-spaces, or through the medium of the uveal tract. But when you have a patient wounded in the ciliary region always give a guarded prognosis; look upon it as an injury fraught with the greatest danger, and which may culminate in the most serious consequences.

The patient has refused to submit to the operation. We shall order him a solution of atropia, grs. iv to ℥j. Internally, we shall give him hydrarg. chlor. mit., grs. ij, pulv. opii, gr. ¾, twice daily. This treatment to be watched. If the eye becomes painful, leeches will alleviate.

P. S.—The patient was brought to the hospital May 21, 1884, by his attending physician, Dr. Fretz, suffering

with the following conditions: Eye much inflamed, cornea hazy, no reflex from fundus obtainable, marked circumscribed ciliary injection, dread of light, excessive lachrymation, tenderness on pressure, pain extending down track of infraorbital nerve—this pain has been very severe at night for the last ten days. The patient consented to have the eye enucleated, which was then done.

The eye was opened. The vitreous turbid; a large, semi-organized blood-clot and exudation in the region of the wound. Imbedded in the exudation was found a flat, rectangular piece of steel, 4 x 6 millimetres. The lens transparent; ciliary bodies and peripheral part of iris much inflamed. The optic nerve and macular region to the aided eye did not seem to be swollen. No sympathetic symptoms in right eye.

STUDY OF THE PATHOLOGICAL CHANGES OCCURRING IN TRIFACIAL NEURALGIA,

WITH THE REPORT OF A CASE IN WHICH THREE INCHES OF THE INFERIOR DENTAL NERVE WERE EXCISED.[1]

BY J. EWING MEARS, M.D.,
PROFESSOR OF ANATOMY AND SURGERY IN THE PENNA. COLLEGE OF DENTAL SURGERY; SURGEON TO ST. MARY'S HOSPITAL, PHILADELPHIA, ETC.

AN examination, somewhat extended, of the literature relating to neuralgia of the fifth nerve has shown that in those cases in which resort has been had to the employment of surgical procedures as methods of treatment, no investigations, or, if any, very incomplete investigations have been made to determine the character of the pathological changes which have been present and upon which the morbid conditions have been founded. Thus, of twenty-four cases reported by Mr. Thomas F. Chavasse to the Royal Medical and Surgical Society of London, in which surgical operations had been performed, but two reports, and these very incomplete, were made of the condition of the nerve involved. The absence of these investigations has interfered, it seems to me, materially with any radical progress in the application of remedial measures and has resulted largely in the use of those which are empirical in character. Believing that we can arrive only at rational methods of treatment by increasing our knowledge of the pathological conditions which exist in cases of chronic prosopalgia, I have ventured to submit the report of a case in which free neurectomy was performed, and in which a careful study was made of the diseased structure removed.

The patient, a German woman, aged 50 years, consulted me eight years and a half preceding the operation, which was performed on the 27th of August, 1883, for intense neuralgic pain involving the left inferior dental nerve. The pain began in the second bicuspid tooth, which was in a state of caries, and passing backward gradually implicated the remaining teeth, which were sound. The carious tooth was removed without affording relief, and subsequently the remaining teeth with the same result. The treatment instituted at this time afforded but slight relief, and the patient passed from under my care. After an interval of four years she again consulted me, having in the meantime received treatment from a number of physicians, with but transient relief. I found on examination that the area of pain had increased, and that the periods of cessation were diminishing. The prolonged use of various anti-neuralgic remedies, combined with the application of the constant current of electricity availed but little, and I suggested neurectomy, which she declined, and again sought other advice.

Four years and a half later she returned and stated that she was prepared to submit to any operation I deemed necessary to perform, as her life was a burden. She had fallen into the hands of empirics, and had, as she expressed it, passed through "fire and water" without relief of the pain, which was now constant and excruciating.

The disease had now assumed the epileptiform variety, the paroxysms occurring at intervals of a quarter and a half of a minute, and were excited by a breath of air, the touch of the fingers, or the placing of food or water within the mouth in contact with the side affected.

On the 27th of August, 1883, I performed neurectomy, removing three inches of the inferior dental nerve including all of it which was contained within the canal and a portion extending beyond the mental foramen shown in Fig. 1. The external surface of the bone was exposed by an incision carried from the middle of the posterior border of the ramus along the base to a point beyond the position of the mental foramen and reflecting the flap.

A one-half inch trephine was applied over the position of the inferior dental foramen and a disk of bone, including the outer table, was removed. The mental nerve was dissected to the distance of a half inch beyond its point of exit from the foramen and divided. A dental burr attached to the surgical engine was now used to enlarge the mental foramen and release the nerve. Traction was made upon the nerve at the point where it was exposed by the trephine and it was withdrawn entire from the canal. Before dividing it posteriorily it was drawn down so that the division might be made as high up as possible and the stump was pushed back until it was entirely beyond the foramen. The artery, which was torn in the manipulations employed to remove the nerve, was divided and the end twisted—no hemorrhage followed. An examination of the nerve in its position in the canal showed that it was swollen and reddened, and the artery appeared to be so compressed and flattened that it occupied very much less of its relative space in the canal. The facial artery was caught by an acupressure needle and held until the completion of the operation, when a ligature was applied. The wound healed in six days. The patient was free from pain, and, with the exception of one or two spasms of pain occurring apparently in the stump of the nerve, she has remained so until this date, nearly nine months.

The opportunity being presented of studying the

[1] Read before the American Surgical Association, May 2, 1884.

conditions which follow the removal of so large a section of the nerve. I made, ten weeks after the operation, two careful examinations of the parts supplied by it, the last examination being made in conjunction with Dr. J. T. Eskridge, of Philadelphia. On the day of this examination, November 9, 1883, the weather was damp, and the surrounding atmosphere 65° F. Over the external surface of the lower lip, comprising the area of terminal distribution of the mental branch of the left inferior dental nerve, a sharply defined zone of complete anæsthesia and analgesia was found. This anæsthetic area was irregular in shape, and measured transversely at margin of lip $1\frac{3}{16}$ inches; at the lower border of the zone (a slightly curved line) $\frac{5}{16}$ of an inch; vertically $1\frac{1}{2}$ inches: transversely at the middle $1\frac{1}{16}$ inches; border over symphysis (slightly convex line), $1\frac{5}{16}$ inches; at external margin towards ramus (slightly concave line), $1\frac{5}{16}$ inches; over this zone the patient was unable to recognize contact of cold or hot substances. Over a small portion of the lip, and outer surface of the alveolar border, corresponding to the anæsthetic area just described, anæsthesia and analgesia were complete. The inner surface of the alveolar border was everywhere sensitive. Over a limited area, extending forwards from the position of the inferior dental foramen to the posterior border of the zone of complete anæsthesia, the ability to recognize tactile sensations, painful impressions, and the contact of heat and cold was diminished. Considerable swelling was noticeable on the left side of the face, with slight drooping of the eyelids, and partial obliteration of the vertical fold extending downwards from the angle of the mouth. The surface of the skin was roughened, and presented the appearance of a somewhat diffuse capillary congestion. Formication was present, and was especially marked on passing from the cold air outside to the warm rooms of the house.

The following surface temperature observations were made, beginning at 11.29 A. M., and continuing until 12.32 P. M.:

Axillary temperature: right, 98°; left, 98°.

Over infraorbital foramen: right, 98.1°; left, 98.1°.

Over inferior dental foramen: right, 97.7°; left, 97.9°—$\frac{2}{10}$° difference.

Near upper border of lower lip: right, 97.4°; left, 97.7°—$\frac{3}{10}$° difference.

Incisive fossa about the middle of anæsthetic zone: right, 96.4°; left, 97.2°—$\frac{8}{10}$° difference.

From the above examination, information was gained as to the area of surface supplied by the terminal branches of the inferior dental nerve, and which, in diseased conditions of the nerve, become the seat of the painful impressions. The existence of slight paralysis of the orbicular and cheek muscles would seem to indicate that by reason of the free anastomoses (correctly speaking unions, or connections) between the terminal branches of the fifth and facial nerves, the excision of a branch of the former had apparently affected the function of the terminal branches of the latter. The incision made did not divide any of the larger branches of the facial nerve, and certainly none of those distributed to the orbicular muscle of the eye. In the same manner as above, may we not explain the painful spasm which occurs in prosopalgia of the epileptiform variety, the facial muscles acting under the motor impulses created by the transmission of the morbid impressions from the diseased sensitive, to the normal motor nerve?

The slight elevation in temperature noted at different points in the anæsthetic zone is in accord with the physiological results obtained after nerve-sections, although Dr. S. Weir Mitchell observes, in his work on *Injuries of Nerves* (edition of 1872), that he is not aware of any clinical observation which records the early rise in temperature after total section of the main nerve of a member. The elevation in temperature is explained as the result of dilatation of the bloodvessels caused by the vaso-motor paralysis.

The portion of nerve exsected was given for careful examination to Dr. G. de Schweinitz, of Philadelphia, who submitted the following report:

"Macroscopically, the portion of nerve presented for examination did not exhibit any changes except, perhaps, a slight thickening beyond what is usual in the normal inferior dental nerve. The thickest portion of the excised nerve corresponded in size to a No. 7 bougie (French scale), and the thinnest to that of a No. 6. The nerve was hardened for section by placing it in Müller's fluid, and then in ordinary alcohol for two days. Transverse and horizontal sections were made and stained with Klein's carmine and hematoxylin solutions, dehydrated in alcohol, cleared up in oil of cloves, and permanently mounted in dammar. For the purposes of comparison, similar sections of a normal external branch of the radial nerve were made after it had been subjected to a precisely similar hardening process.

FIG. 1.

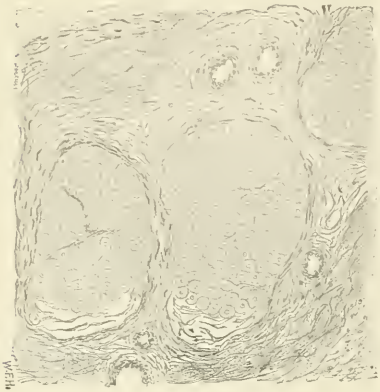
The portion of the nerve removed.

"In Fig. 2, within the perineurium, are seen the cross-cuts of the nerve-fibres, separated from one another by the delicate tissue known as endoneurium, which is here and there crossed by fine trabeculæ of connective tissue subdividing the fasciculus. Each nerve-fibre is composed of a dark, central spot representing the axis-cylinder surrounded by a white circle—the medullary sheath. The whole is enclosed within a double contoured external ring, the sheath of Schwann or neurilemma. The supplying bloodvessels are seen in cross-section in the connective-tissue investments of the nerve.

"Figs. 3 and 4 represent the microscopic characters of the diseased nerve. Some slight increase and thickening of the connective-tissue sheaths investing the fasciculi as well as of the trabeculæ

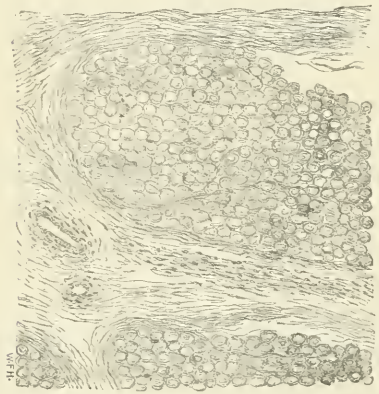
dividing them is noted, together with a change in their regular arrangement. The walls of the blood-

FIG. 2.



Cross-section of the normal external branch of the radial nerve. Cross-sections of the individual nerve-fibres are seen, showing axis-cylinder, medullary sheath, and neurilemma. The fasciculi are subdivided by trabeculæ of connective tissue. Bloodvessels are seen in cross-section.

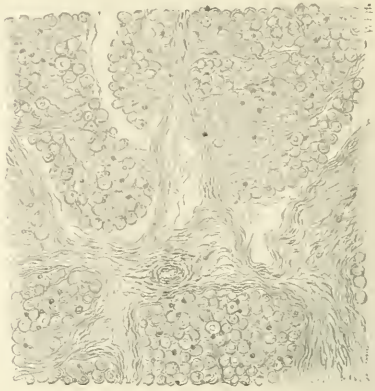
FIG. 3.



Section of the diseased nerve taken from near the mental foramen. The irregular and confused outlines of the nerve-tube are shown, together with the concentric arrangement of the arches. The connective tissue is moderately thickened. Three bloodvessels are seen, two in cross-section, and one longitudinally, surrounded by small-celled lymphoid infiltrate showing thickened walls.

vessels, both in cross-section and in Fig. 3, when viewed in vertical section, are surrounded by a lymphoid infiltrate. Here and there, scattered through the connective tissue, are small collections of minute,

FIG. 4.



Section of the diseased nerve taken from near angle of the jaw. Changes the same as those above, only less marked. Here and there nerve-tubes of normal appearance are noted. The same concentric arrangement, and also alteration in bloodvessels, is seen.

yellowish-white, glistening dots representing probably foci of fatty degeneration. The chief changes are in the nerve-tubes themselves. The axis-cylinders cannot be satisfactorily demonstrated. When present they are not stained with carmine, and are often apparently entirely wanting. The medullary sheath appears swollen and the cross-cuts of the individual nerve-fibres are not clearly defined and sharply cut, but consist of a confused mass of concentric rings. The sheath of Schwann often has a crumpled appearance. The transverse sections of the nerve-fibres might in many places be not incorrectly compared to the interior aspect of a minute oyster-shell both in shape and by virtue of this peculiar concentric arrangement. Longitudinal sections reveal increase of the nuclei of the sheath of Schwann. The changes thus described show a parenchymatous neuritis, as is indicated by the degeneration in the nerve-fibres as well as changes in the connective tissue of an inflammatory type, as is shown by its thickening and the alterations in and about the bloodvessels. The neuritis is probably also of an ascending nature, as the changes in the diseased nerve are more marked about the mental foramen and grow less noticeable as the angle of the jaw is approached."

It has been observed that the anatomical distribution or rather arrangement of the large nerve-trunks of the body, is such that they are protected by position from injury. Thus, those of the upper and lower extremities are placed, where they enter the parts and are superficial, on the inner aspects—in the forearm and leg they are covered by muscular

masses, and in passing to their terminal distributions they are surrounded by fascial envelopes which more or less protect them. Notwithstanding the protection afforded, there are certain nerves in which chronic forms of neuralgia appear which are very often traumatic in origin. Thus, the sciatic nerve may be readily injured at the point of emergence from the pelvic cavity—the sacro-ischiatic notch—by falls and kicks, giving rise to inflammatory conditions and resulting degenerative changes, and in this manner we may explain the frequent occurrence of its diseased states. The median nerve is exposed to injury in deep wounds of palm of the hands by wounds from knives, glass, splinters, etc.

In *The American Journal of the Medical Sciences* for July, 1874, Dr. S. Weir Mitchell reported a case of traumatic neuralgia of the median nerve due to a wound of one of the palmar branches by a splinter. Twenty years after, a bruise of the palm developed intense pain in the course of the terminal branches of the nerve and the splinter was removed. The pain continuing, three-quarters of an inch of the nerve was excised, with permanent relief to pain. An examination of the exsected nerve showed marked degenerative changes which had occurred primarily in the nerve-fibres themselves.

Of all of the cranial nerves, the fifth is, by reason of its anatomical distribution and relations, most exposed to injury and to morbid changes. Appearing upon the external surface by large terminal branches, at three exposed points it may suffer injury by blows and falls. Much stress has been, from time to time, laid upon the fact of the passage of the branches of the nerve through bony canals and notches and the contractions of these channels by inflammatory changes have been assigned as the not infrequent causes of painful conditions. A specimen of hyperostosis of the lower jaw in my possession would seem to show that in changes of this character marked contraction does not occur; the hypertrophy in this case was due to syphilitic periostitis, the patient dying of syphilitic gumma of the brain; during life neuralgic symptoms were absent. In cases of phosphorus necrosis of the lower jaw, in which the disease originating in specific inflammation of the periosteum results in the deposit of layers of ossific matter, the foramina of entrance and exit of the inferior dental nerve are not markedly encroached upon, and neuralgic conditions are not a usual accompaniment of the disease according to my observation, which has recently been somewhat extensive. That the presence of the nerve-branches, with bloodvessels in these bony canals, contribute to morbid conditions which have been developed we will discuss further on. It is, I think, in accordance with the conservatism which attends the progress of structural changes to afford protection to the bloodvessels and nerves, in order that nutrition may be maintained.

The direct and extended connections of the nerve through two of its divisions with the teeth, offers, it seems to me, a satisfactory explanation as to the frequent occurrence of neuralgic conditions. Not only may the morbid conditions take origin in the ultimate nerve-twigs which take part in the formation of the pulp, but also in the filaments distributed to the alveoli and their vascular and sensitive lining membrane. Inflammation of this lining membrane may occur without accompanying caries, and in this manner we may explain the presence of pain in teeth which are sound, and also the temporary relief which follows their extraction.

Inflammation beginning in the twigs of the pulp and permitted to continue, may pass by continuity of structure to the trunk of supply, and gradually involve it. At first, the connective-tissue structures of the nerve become the seat of the inflammatory changes, resulting in hyperplasia and increase in size. The continuance of the inflammatory action results in interference with nutrition, and degenerative lesions are developed. To what extent the interference with nutrition is due to the cutting off of the blood-supply from the accompanying artery by pressure of the abnormally enlarged nerve is a question of interest. And whether the defects of nutrition are entirely intrinsic, resulting from the hyperplastic changes in the nerve itself, is a subject for further study. In the case under examination it will be recalled that the artery, as it lay in the canal with the somewhat enlarged nerve, appeared compressed and its walls collapsed.

The discussion as to the origin of chronic neuralgic affections of the fifth nerve in peripheral or central lesions has taken place from time to time. That grave central lesions in the nerve, or intracranial conditions, may cause intense painful affections cannot be questioned. Dr. Roberts Bartholow, in his *Practice of Medicine*, states that he has observed the most intractable neuralgia, involving the intraorbital branch of the second division of the fifth nerve, which was found, post mortem, to be due to an intracranial aneurism exerting pressure upon the nerve before its exit. The evidence deduced from the great majority of reported cases, however, confirms the belief that the lesions are, in their origin, peripheral in character.

Another question of interest, which has been discussed in connection with neuralgic affections involving the intraorbital branch, has been the involvement of the ganglion of Meckel and the necessity for its removal in operations. This question, it seems to me, should not demand very serious discussion, and the statements which have been made in reported cases have lacked elements of evidence which should give reason for their acceptance. The cephalic ganglia of the sympathetic system, four in number, are all in relation with the fifth nerve through the sensory roots which this nerve contributes to them. It is possible that the roots derived from the nerve-trunk might become implicated by continuity of structure, but we have no evidence that this involvement of the roots leads of necessity to a morbid state of the ganglion, which differs in structure from the nerve-fibres. Further involvement of the ganglion would induce morbid impressions, which would manifest themselves in the branches of distribution, and we should expect to find symptoms in the cavities of the nose and mouth, which receive these branches largely. Our knowledge of the symptoms expressed in the ganglia of the sympathetic system in morbid states is too meagre to permit the acceptance of the opinion that the painful impressions occurring in neuralgia of

the superior maxillary division of the nerve take their origin in the ganglion, and that its removal with the nerve is demanded, in order to secure permanent relief. We do know that the sympathetic system is endowed both with sensibility and the power of exciting motion, but these properties are less active than in the cerebro-spinal system, and are exercised in a different manner.

The propositions which I would submit as the result of the study of the case reported are as follows:

1. That in the large majority of cases of chronic prosopalgia, the infraorbital and inferior dental branches of the fifth nerve are implicated, and that these branches are involved to the exclusion of other branches of the second and third divisions of the nerve.

2. That as the filaments of these branches terminate in the teeth and the alveoli which contain them, we must look for the initial lesions in morbid conditions of these organs.

3. That these initial lesions are essentially inflammatory in character, assuming the form of an ascending neuritis, and that non-interference with the progress of the action results in secondary degeneration, the ultimate expression of which is that of fatty degeneration.

4. That the diffused character of the pain and the painful spasms observed in the epileptiform variety are due to the extensive connections of these branches with those of the facial nerve.

5. That if involvement of the sympathetic ganglia occurs it is secondary in character, and that we have no positive evidence that independent removal of these structures will afford relief in the treatment, or that their removal with the nerve is essential to permanent relief.

6. That the treatment should be divided into that of two stages, primary and secondary. It should consist in the primary stage of the removal of the causes by proper treatment, and the employment of antiphlogistic remedies. Destruction of the nerve-filaments and filling of the cavities, or extraction of the teeth and treatment of the lining membrane of the alveoli should constitute the treatment in the early periods of the primary stage.

Ligature of the common carotid artery as advised by Weinlechner and Patruban, and as has been practised in a number of reported cases, should be performed in the early period of the primary stage before the deposit of plastic matter, in order to be of avail. As the vascular supply to the nerve is derived from the branches of the external carotid, it would appear as sufficient to apply the ligature to this vessel just below the origin of the facial. Owing to the free anastomosis between the terminal branches of the arteries, it would require ligature of both arteries, in order to be completely effective. The ligature of the artery supplying the nerves involved is in accord with a rational method of treatment of the inflammatory condition, and the absence of permanent relief in cases in which it has been employed has no doubt been due to the fact that the operation was not performed at a sufficiently early period.

Stretching of the nerve is an operation which should be performed in the later portion of the primary stage, and beginning of the secondary stage, after the deposit of exudates; the purpose being not only to destroy the conducting property of the nerve, but to break up the deposit, in order that its removal may be more readily accomplished by absorption. The failure of this method of treatment in cases reported has been due probably to the fact that it has been performed too late, when the ultimate degenerative changes have taken place.

Neurotomy may be regarded as of little, or no value in obtaining anything but the most transient relief, the speedy reunion of the divided nerve soon restoring the morbid conditions. The timely depletion which may follow division in the very early stage may be of service, but nothing can be expected, so far as permanent relief is concerned, in the secondary stage.

I have recently had under my care a case in which the effects produced by nerve-stretching were well illustrated, and which may occur in prosopalgia when treated by this plan. The patient a German, aged thirty-eight, fell in going down stairs, and received a wound of the upper part of the palm of the hand by the breaking of a lamp which he held. Beyond washing the wound nothing was done in the way of treatment. In a few days it healed, leaving a somewhat painful cicatrix. Gradually the pain extended to the thumb and fingers, and was distinctly felt in the terminal distribution of the median nerve, both sides, thumb, index, and middle finger, and radial side of ring-finger. The pain became intense, and the fingers assumed the clawed position, and any effort to extend them gave rise to excruciating pain. Coming to me for relief I excised the cicatrix, dissected out the nerve to the extent of an inch, removed a small piece of glass which lay beneath it and stretched it forcibly; at once this removed a distinct enlargement which existed upon the nerve at the point of wound, and also elongated it. Pain was promptly removed and an anæsthetic condition resulted in the area of distribution of the nerve-branches. At the expiration of four months normal sensation began to return, and is now, two months later, perfect. The result in this case indicates that the stretching had destroyed the power of the nerve to conduct painful impressions, and as well, probably, caused a gradual absorption of the infiltrate. This being in time accomplished the conducting power of the nerve was restored and the morbid condition being removed, the impressions were normal in character.

Neurectomy is the operation which should be performed in the secondary stage, and when the epileptiform variety of the disease is present a careful examination should be made, in order to determine, if possible, the extent of involvement, and excision should be carried beyond that point. It should be a rule to leave none of the nerve in the bony canals, and also in intractable cases to carry the operation to the point of exit from the cavity of the cranium. With regard to the second and third divisions, the foramina can be reached in one operation by the method practised by the late Professor Joseph Pancoast. This operation consists in the elevation of the masseter muscle by a square-shaped

flap over the ramus of the jaw, resection of the coronoid process, ligature of the internal maxillary artery, separation of the points of origin of the external pterygoid muscle, and exposure of the oval foramen and the spheno-maxillary fissure. At the former the inferior dental can be divided, and after being exposed by a slight incision can be divided and released at the mental foramen by the surgical burr, and withdrawn entire from the canal. The infraorbital can be hooked down as it crosses the spheno-maxillary fissure, divided, and released at its emergence upon the face in the same manner as the inferior dental at the mental foramen.

If in any case I believed, or had evidence by the symptoms, or by the appearance presented in the branches of the inferior maxillary division, that the morbid condition had invaded the Gasserian ganglion, I would not hesitate to enlarge anteriorly the oval foramen by the application of the burr attached to the surgical engine, and by traction draw down the ganglion from its position in the fossa upon the anterior surface of the apex of the petrous portion of the temporal bone, and proceed in a cautious manner to break it up or remove by section with the small blunt-pointed scissors. The primary ligation of the internal maxillary artery precludes hemorrhage from either the meningea media or parva, the first of which is in intimate relation as it passes through to the foramen spinosum, and the second as it enters the cranial cavity through the oval foramen. The position of the internal carotid artery as it passes from its canal in the petrous portion of the temporal bone into the cavernous groove should not be forgotten, and great care should be taken to avoid injury to it by going beyond and behind the margin of the oval foramen.

Neurectomy, to be successful, should be complete. Incomplete and partial operations not only result in failure, but destroy the confidence of the patient as to the benefit to be derived from operative procedures. I have ventured to bring this subject before the notice of the Fellows of this Association, and I have submitted the report of the results of the examinations in the case under my care, with the hope of stimulating further researches into the pathological conditions which exist in this truly distressing affection. It is only in this way, as I have stated before, that it can be removed from the domain of empiricism, in which it rests without hope, and be placed upon the sure foundation of a rational system of treatment.

CASE OF DERMATITIS HERPETIFORMIS (MULTIFORMIS), AGGRAVATED BY PREGNANCY AND IRREGULAR MENSTRUATION.

By LOUIS A. DUHRING, M.D.,
PROFESSOR OF SKIN DISEASES IN THE UNIVERSITY OF PENNSYLVANIA.

MRS. M., aged twenty-eight, a resident of St. Paul, Minn., consulted me February 3, 1883, for a chronic inflammatory disease of the skin, involving the entire surface. She was of spare frame, with brown hair, and of a nervous temperament. She gave the following clear and interesting history of her case: Her ill-health began three and a half years ago, up to which date she had been in good general health; had menstruated regularly and normally, and had weighed one hundred and thirty-five pounds. She had borne a healthy child three years before, without difficulty. The first manifestations were upon the tongue and in the throat, in the form of whitish spots, similar to so-called "canker-sores," which continued for six months, desquamating from time to time, the mouth being so sore and sensitive as to render eating painful. She was in the third month of her second pregnancy when the first sign of cutaneous disease appeared on the flexor surfaces of the right arm and thigh, and on the abdomen, in the form of small, annular clusters of *vesicles*, occupying the space of a five-cent silver piece. The lesions were itchy from the beginning. They spread slowly, new "little water-blisters" coming out from day to day. This process progressed for six weeks, when the body was well covered with eruption, and she was compelled to remain in bed. Three weeks after the attack began *blebs* appeared, accompanied by comparatively slight itching. They ruptured easily and left excoriated surfaces. As gestation proceeded, the disease became steadily worse, being at its height during the fourth and fifth months, at which date *vesicles* and *blebs* of all sizes were very numerous, and the itching intense, accompanied by extensive excoriations and scratch-marks, with more or less oozing and crusting. No treatment used seemed to have any effect in relieving the symptoms.

At this date very curious lesions were noticed on the wrists and on the palms and soles. They were elongate (about an inch in length), rounded (about an eighth of an inch in thickness), firm, whitish, striated elevations, situated transversely on the wrists, the same condition existing on the palms and soles. When opened a non-offensive, cheesy mass "popped out," to use the words of the patient. The contents were not expressed, but were forced out naturally. The lesions were opened every day for several weeks, when they ceased appearing.

At the sixth month of pregnancy the skin cleared off, the lesions disappearing, except a large bedsore, which did not heal until a month after delivery. The skin remained comparatively clear about one week, when small pin-head-sized *vesicles*, soon followed by large, hazelnut-sized *blebs*, again appeared. This crop also manifested itself on the legs and feet, regions hitherto exempt. The blebs were all large, very abundant, crowded one another, and were very itchy. Some of the lesions became pustular. Three or four weeks before delivery the whole integument became œdematous, swelled, or "puffed up," as she expressed it. This condition gradually subsided a week or ten days after the birth of the child, which was born healthy at full term, but lived only four days.

After delivery, and for three weeks following, the vesicles and blebs became fewer, the skin becoming again entirely clear of eruption, and she regarded herself as cured. She remained free, however, only a few days, when small *pustules*, pin-point in size, appeared in abundance; these disappeared, and were followed by a crop of mixed lesions—of *pustules* and

blebs. This condition continued better and worse, during the winter, the disease towards summer locating itself chiefly about the axillæ and groins, characterized now by an offensive, excoriated, at times weeping, crusted surface, with itching. Through the summer the skin of the palms and soles thickened, beneath which pus formed, undermining it. This continued for three or four months.

In August, 1881, she indulged in a bath, just before the menstrual epoch, after which the face became blotchy, bluish, and swollen, giving her "a dissipated look." Vapor baths taken repeatedly for one month completely exhausted her. September 1st the menses failed to appear, and October 1st there was a slight discharge, at which date she again broke out with variously sized *vesicles* and *blebs*, the latter, for the most part, as large as a hazelnut, many of them having puriform contents. There was now much excoriation and crusting, the bed-linen everywhere adhering to the raw skin. Numerous small, pin-point-sized *vesicles*, closely crowding one another, again came out over the whole surface. They were so abundant that a pin-point could scarcely be put down between them. She was "literally covered with them," and this condition, in the form of crops, lasted all winter.

The skin disease later again changed its character, large *blebs* and *pustules* appearing, especially upon the face, which was much swollen.

The menstrual flow remained absent five months (from October, 1881, to February, 1882). Arsenic in large doses, and later electricity, were used, and it was thought that she was benefited by the latter. Improvement continued slowly but steadily up to July, 1882, when suddenly, and without apparent cause, violent inflammation of the hands and feet, with large *pustules* on the palms and soles and on the face, manifested itself. These continued to appear and to disappear, in crops, through the summer and autumn, up to the present date, the lesions being, as a rule, shot-sized, whitish *pustules*, and *vesicles*, closely crowded together over almost the entire cutaneous surface. Her general condition has been variable. On many occasions she has felt ill, weak, very nervous, depressed, with chilly or heated sensations or rigors. On one occasion the tongue swelled and became coated with a puriform exudation, with profuse salivation. Menstruation when present is usually normal. Her weight now is about ninety-five pounds, forty pounds below her former average. The appetite has always remained good. She has been under the care of a skilful specialist in skin diseases for six months, but has failed to receive any benefit.

The present condition (February 3, 1883) is as follows: The whole general surface is the seat of a subacute and chronic inflammatory *erythematous* (somewhat urticarial), *papular*, *papulo-vesicular*, *vesicular*, and *pustular* eruption, the lesions being very markedly multiform. They are pin-point, pin-head, and pea-sized; are thickly studded; are firm, and have a shotty feel, as in the early stage of variola. The skin is everywhere much thickened, and is even tough and leathery, and is markedly pigmented, being of a mottled, reddish, dirty-yellowish, brownish hue. The eruption is *intensely itchy*. The face and scalp are least affected, but, as stated, the rest of the general surface, including the palms and soles, is well covered with primary and secondary lesions.

The patient was ordered for local use an ointment of precipitated sulphur, two drachms to the ounce, to be applied to the right half of the body; to the left half, an alcoholic solution of coal-tar, diluted one to four or eight parts of water. Internally, a mixture containing sulphate of magnesium, three ounces; bitartrate of potassium, six drachms; precipitated sulphur, one drachm; glycerine, four fluid-drachms; peppermint water, four fluidounces. Dose, a half fluidounce with a gobletful of water before breakfast. Also, a preparation of iron, bark, and arsenic (one minim dose), to be taken thrice daily. At night a mixture of chloral and bromide of potassium. Both local remedies acted happily, and for five days no preference for one or the other was expressed by the patient. A few days later more improvement was observed upon the side where the tarry solution had been used, and this was then applied, full strength, to the whole surface. Both remedies also had immediate and positive effect in relieving the distressing itching. The skin began to improve, and the eruption to decrease within several days after the treatment was instituted, and at the end of a fortnight very decided benefit was noticeable in the condition of both the general health and the skin. She was well enough a month later to return home, since which time I have heard nothing from her.

The history of the case, extending over three years, shows well the protean character and the multiformity of the disease. It shows the simultaneous occurrence at several periods in the course of the process of erythematous patches, maculo-papules, papular infiltrations, vesico-papules, vesicles, blebs and pustules. At other periods vesicles and blebs prevailed; sometimes vesicles and pustules; and occasionally vesicles, blebs and pustules. The lesions were always accompanied by severe itching and more or less burning. Constitutional symptoms at times were marked, consisting of rigors, sensations of alternate heat and cold, and febrile and nervous symptoms. The latter were especially prominent.

The disease of the skin was unquestionably due partly to the depraved condition of general health preceding pregnancy, but more particularly to this latter state itself. It will be remembered that the cutaneous manifestations appeared in the third month of gestation. It was without doubt subsequently kept up by the disordered condition of the menstrual function and the accompanying disturbed nervous system.

At present I shall not consider the disease further than to say that the case may be regarded as representing the multiform variety of dermatitis herpetiformis. Noted at one period, it would have illustrated the vesicular or the papular variety; at another time, the bullous variety; again, the erythematous; while more often, however, the condition was one of multiformity of lesion, including at times the abundant development of peculiar pustules. The

latter phase is that which was first described by Hebra as "impetigo herpetiformis." The vesicular variety has figured conspicuously of late years under the head of "herpes gestationis." In a paper recently read before the American Medical Association, I have described dermatitis herpetiformis at length, giving its characteristic features together with its more prominent varieties or phases.[1] I think both the impetigo herpetiformis of Hebra, and the herpes gestationis of authors, should be placed under dermatitis herpetiformis, both being mere varieties of one pathological process.

The case just considered shows the disease in a severe form, characterized by marked constitutional symptoms; profuse eruption, multiform in character, and appearing in crops; extensive secondary changes in the skin; and itching and burning of the most distressing kind. The patient suffered greatly, the disease for a long period being most rebellious to treatment. Concerning the diagnosis, I may add that as the eruption was noted as one or another set of lesions was out, the disease might easily have been confounded with eczema, herpes or pemphigus; but, keeping the history in mind and observing the course of the process for some time, the individuality of the disease always asserted itself. It is a distinct and clearly defined disease, which, when once recognized, cannot be confounded with any of the well-known skin diseases.

HOSPITAL NOTES.

MEMORIAL HOSPITAL, ORANGE, N. J.

Service of WILLIAM PIERSON, M.D.

A TRIAL OF RECTAL ANÆSTHESIA.

(Reported by DR. J. H. BRADSHAW.)

MICHAEL F., aged 22, single, hatter. The patient, some weeks previous to the time at which the trial of this new method of producing anæsthesia was made, had suffered from a contused and lacerated wound of left middle finger. There had been no injury to the bones, and the wound implicated only the last phalanx. This injury had been treated at the hospital, it had well healed, and the patient had been discharged. He, however, returned to the hospital in a few days with the following story: Having seen the nurses irrigate his wound with a disinfectant solution of carbolic acid, (1–40), he had, in order to cleanse some dirt from the finely cicatrizing surface, bought some pure carbolic acid and had *held* his finger in this undiluted acid. The result was a moist gangrene extending almost to the metacarpus.

Amputation of the finger being necessary, it was decided to attempt the rectal method of producing anæsthesia, advocated a month or two since by Dr. Molière in the *Lyon Medical*.

An apparatus was extemporaneously prepared, consisting of a bottle, a rubber stopper, and two glass tubes passing through the latter. To one tube were attached eighteen inches of rubber tubing, on the extremity of which was placed the nozzle of a Davidson syringe to be introduced into the rectum. To the projecting end of the second tube was fitted a cork, which was to be removed whenever additional ether was to be put in the bottle. It was subsequently found necessary to replace the syringe nozzle by a No. 18 hard but flexible catheter whose tip had been cut away transversely.

Patient tasted the ether, and it was perceptible in his breath within seven minutes after the introduction of the tube. Anæsthesia was complete in eighteen minutes. The amount of ether used was seven ounces. The operation itself lasted but eight minutes, after which the tube was removed and the patient speedily recovered.

Soon after beginning to give the ether the face was somewhat suffused. While under its full influence the pupils were dilated. Breathing was natural and easy, and without stertor. There was, of course, no sense of strangulation, and during the administration there were no unpleasant symptoms other than a slight fulness of the abdomen, and a somewhat warm feeling in the intestines. Patient had eaten a hearty breakfast four hours before given the ether, and during and after the operation there was no nausea or vomiting. There was no stage of excitement preceding the stage of insensibility; however, the patient was very talkative when coming to himself.

During the operation the patient answered questions in an amazingly rational manner, but when he recovered from the effects of the anæsthetic he said he had felt no pain, had suffered no disagreeable feelings, but it had seemed to him "as if he had just awakened from a pleasant dream."

The operation took place May 6th, at noon, Dr. Pierson operating, and Drs. Chandler, Wickes, Stickler, and the writer, being present. The finger was removed at the metacarpo-phalangeal joint. Two hours after recovering from the ether the patient took ℥vj milk and one egg; respiration 28; pulse 92; temp. 98½°. Three hours after operation the patient had a large, natural movement, and passed ℥iij urine. One hour later he began to get strangely drowsy and violent colicky pains were referred to the abdomen. Four hours and a half after giving the ether the patient began to vomit and threw up about ℥x of the contents of stomach. One hour later had a large bloody stool and also vomited blood. Pain severe. Resp. 24; pulse 80; temp. 99½°.

Six hours after the operation pain was "unbearable." Patient vomited everything taken into his stomach. About every hour from this time he either vomited or passed blood from the bowels. Large quantities of pure blood were thus evacuated. Patient grew very prostrate.

Twenty-four hours after the operation the following observations were made: resp. 28; pulse 126; temp. 104°. Four hours later: resp. 23; pulse 126; temp. 104¾°. One hour after this the patient's condition was indeed alarming: temp. 104¼°; pulse 160, and almost imperceptible; resp. 32; prostration excessive. Evacuations of blood continued; patient's condition remained alarmingly low during the second night, the pulse being very feeble and irregular, and the temperature remaining high. Symptoms of gastro-enteritis continued. Urine drawn off by catheter. Forty-eight

[1] Abstracts of this communication may be found in the N. Y. Med. Journ., May 17, 1884, p. 562, and in the Phila. Med. Times, May 17, 1884, p. 603.

hours after the administration of the ether the patient's condition was somewhat less alarming. But the temperature remained about 102°.

It was not until the evening of May 10th, the fourth day after the operation, that the temperature fell to the normal, and the patient began to make a slow recovery.

During this long period of danger everything was done to ameliorate the condition of the patient and to keep him alive. There were administered: enemata of ice water, of starch, of catechu, of quinine, and of opium; cold baths during the pyrexia; injections of Magendie's solution by the skin; tincture of digitalis, quinine, Dover's powder, bismuth, and lime-water by mouth to meet these indications, and milk, beef-tea, and whiskey at short intervals. Physicians or trained nurses were in constant attendance.

May 20. The patient is just strong enough to be about. The healing of the wound has been unsatisfactory.

Remarks.—This far from gratifying endeavor to give Molière's method a fair trial, it is thought wise to put on record, It is true more ether was used than is usually found necessary to employ. But this is accounted for by the fact that for the first five minutes of the administration, owing to defects in the apparatus, no ether passed into the rectum; thus the quantity of ether used and the duration of the process are both over-estimated. It is not thought probable that the injudicious use of carbolic acid by the patient influenced the result of the trial, for the patient was in good physical condition and gave no constitutional evidence of poisoning by carbolic acid.

MEDICAL PROGRESS.

Nephrectomy.—At the meeting of the Glasgow Pathological and Clinical Society, on March 25th, Dr. Macewen presented a boy from whom the right kidney had been removed about ten weeks previously, on account of suppuration of that organ, which had extended so far as to have virtually destroyed its excretory function. He had previously suffered for many months from symptoms of renal calculus. When admitted under Dr. Macewen's care he was in a semi-delirious and very exhausted condition, with flickering, feeble pulse and abnormal temperature, lividity of face and lips. On examining the small quantity of urine obtained on admission, it was seen to have a copious deposit of pus. On microscopic examination tube-casts containing pus-corpuscles were found, besides numerous crystals of phosphate of lime. There was an increased area of renal dulness on the right side, and a marked fulness in the lumbar region. He was at once operated on by lumbar incision. After removing a large quantity of fetid pus (swarming with bacteria) and shreds of sloughing cellular tissue, two renal calculi were detected in the kidney, one of which occluded the ureter and occupied the greater part of the pelvis, the other in the substance of the organ. Both were removed, but, on further examination, the whole organ was found to be filled with abscesses, leaving little or no excretory surface. It was therefore removed. After recovering from the shock of the operation, he progressed with astonishing rapidity.—*Glasgow Med. Journ.*, June, 1884.

The Phosphorus Treatment of Rickets.—Dr. M. Kassowitz, after repeating the experiments of Wegner on rabbits and chickens, as to the influence of phosphorus on ossification and bone-formation, draws the following conclusions:

1. Large doses of phosphorus cause, in rabbits and chickens, an inflammatory process in the bones, the ossifying cartilages, the periosteum, and the medulla, which bears a striking resemblance, when in a moderate degree, to the rachitic affection; whilst, by an increase of this inflammatory process the epiphyseal cartilages are separated from the diaphyses.

2. Very small doses of phosphorus limit, in a striking manner, the breaking down of the ossifying cartilages and of the newly formed osseous plates, and cause a decrease in the number of primary medullary cavities, as well as a diminution of the later phenomena, which must necessarily lead to a checking of the development of new bloodvessels, and very probably to a contraction of their walls.

The practical results of these experiments have been tested on 360 children ranging from eight months to two years of age, and Kassowitz now believes that phosphorus is a direct, if not a specific, remedy for rickets. All the symptoms of the disease improve under the phosphorus treatment. It may be given in doses of from gr. $\frac{1}{180}$ to $\frac{1}{45}$ or $\frac{1}{32}$ according to the age of the patient. The following is a convenient formula:

℞.—Phosphori, .01 part by weight, solve in olei amygdalarum dulc. ant. ol. oliv. 10.

Pulv. gummi acac.,
Syrup. simpl., ... āā 5.
Aquæ destill., ... 80.

Sig.—Dose, one to four small teaspoonfuls daily.

Or, we may use 100 parts of cod-liver oil and .01 part, by weight, of phosphorus, giving one or two teaspoonfuls a day; or, oil of sweet almonds 70, phosphorus .01, powered white sugar 20 parts by weight, ether 20 drops. One or two teaspoonfuls a day; or, oil of sweet almonds 30, phosphorus .01, powered gum-arabic and white sugar āā 15, distilled water 40 parts by weight. Dose, one or two teaspoonfuls a day.—*Deutsche med. Wochenschrift*, April 3, 1884.

Physiological Effects of Amorphous Digitaline.—M. Kaufmann, Chief of the Physiological Laboratory in the Veterinary School at Lyons, draws the following conclusions at the close of an elaborate article on this subject:

1. Digitaline does not cause diuresis, either in large or small doses, when given to healthy animals. Given by hypodermatic injections, or by the stomach, in the form of powder, it diminishes the quantity of urine, and increases the quantity of urea; given by the stomach, in liquid form and in small doses, it diminishes the amount of urea and of uric acid. It produces diuresis only in dropsies arising from circulatory troubles.

2. Digitaline acts as an energetic local irritant. Its general effects are most marked when dilute solutions are injected into a vein, or placed in the trachea or stomach; subcutaneous and intramuscular injections cause a fever of reaction.

3. Digitaline, in small doses, causes slowing of the pulse, followed by an acceleration when medium and

large doses are given. The slowing of the heart is due to bulbar and intracardiac irritation of the inhibitory system, and the acceleration is due to central paralysis of this system.

4. It increases the diastolic and systolic intracardiac pressure, and therefore the mechanical work of the heart. It gives an increased energy to the cardiac contractions, and increases the wave-volume.

5. During the slowing period, the cardiac contractions are often associated two or three together. During the acceleration the heart-beats are regular.

6. With small doses the pulse becomes stronger; with large doses it is at first strong, afterwards feeble. It often becomes double or threefold.

7. Small doses slightly increase the arterial tension by central and peripheral excitation of the vaso-motors; larger doses increase it at first, but it subsequently diminishes.

8. It diminishes the rate of flow through the arteries; it reduces the rectal temperature; and diminishes the quantity of urinary secretion in a healthy animal.—*Revue de Médecine*, May, 1884.

Spondelolisthesis.—Swedelin, after giving a detailed report of a personal observation, studies the termination of labor in all cases of spondelolisthesis known at present, and draws the following conclusions:

1. In contractions of slight degree, caused by olisthesis, the pseudo-true conjugate being less than three and three-fifths inches, delivery is not generally difficult.

2. In medium contractions, the pseudo-true conjugate being from three to three and three-fifths inches, labor at term is not generally serious for the mother and child. Very serious intervention is rarely necessary.

3. In very pronounced contractions, the pseudo conjugate being from two and three-fifths to three inches, labor at term is very serious for the child. The prognosis for the mother is not quite so unfavorable.

4. In extreme contractions, the pseudo conjugate being less than two and three-fifths inches, the head of the fœtus cannot pass without an operation.

5. For multipara, the prognosis of the expected labor is more serious as previous labors have been difficult.

As regards operative indications:

1. When the pseudo-true conjugate diameter is less than two and four-fifths inches, labor should be brought on in the thirty-second week.

2. When the pseudo-true conjugate is between two and four-fifths and three and one-fifth inches, labor should be brought on in the thirty-sixth week.

3. When the diameter is from three and one-fifth to three and three-fifths inches, the pregnancy may be allowed to go to term, unless there are no reasons for believing that it will terminate favorably, or the woman is depreciated in health by the pregnancy, in which case it is better to bring on labor in the thirty-sixth week. If the diameter is more than three and three-fifths inches, premature artificial delivery is not indicated.

4. When the pregnancy has gone on to term, one should hesitate, even with a pseudo-true conjugate of less than two and four-fifths inches, before operating on the fœtus, unless the mother is endangered, and then cranioclasty should be the choice. Cæsarean section should be the second choice. With a pseudo-true conjugate of two and two-fifths inches, the Cæsarean operation is indicated.—*Archives de Tocologie*, March, 1884.

Sclerotinic Acid in Epilepsy.—The preparations of ergot have already been used, with more or less success, in the treatment of epilepsy, but sclerotinic acid was first used by MM. Bourneville and Bricon, in 1882. They now administer it either in julep or hypodermatically.

In December, 1882, four epileptic children were treated with the following solution:

℞.—Sclerotinic acid, . . grs. vijss to xss.
Distilled water, . . f℥ijsss.
Carbolic acid. . . . grs. xss.—M.
S. Each injection should contain from gr. $\frac{1}{25}$ to $\frac{1}{12}$.

For hypodermatic use, the dose has not been greater than gr. $\frac{1}{12}$. The duration of the treatment was six weeks for one child, which died; six and a half months for two others, and seven months for the fourth.

For internal administration, the acid is given in an aromatic adjuvant (*julep*), morning and evening. Eight epileptics have been treated in this manner, the dose of sclerotinic acid progressively increasing by about gr. $\frac{1}{8}$ every week. The average duration of treatment for these eight patients was three hundred and fourteen days. Of the twelve patients treated by both methods, only five have been improved. These results are not very encouraging, but, under the circumstances, it may be worth while to experiment still further with this drug.—*Le Progrès Méd.*, May 24, 1884.

Removal of Astragalus for Fungous Osteo-arthritis of the Ankle-joint.—M. Robert, at the close of an interesting article on this subject, draws the following conclusions:

1. Sprain of the foot is frequently followed by chronic bone lesions, which have a great tendency to be localized in the astragalus, or in the articular surfaces of the astragalus or calcaneum.

2. These lesions may be for a long while limited to the region of the tarsus, yet the simple means directed against the osteo-arthritis are often powerless—modifying injections and ignipuncture being usually inefficacious. Gouging, scraping, and deep cauterization are not certain methods for reaching the seat of the disease, and sometimes cause such an aggravation that amputation becomes necessary.

3. Removal of the astragalus is an operation which facilitates exploration of the articular surfaces affected with caries, and which enables the operator easily to remove the diseased parts. When done by Vogt's method, it is easy, causes no severe injury, has only a small mortality, gives permanent cures, and, at times, excellent functional results.

4. As with all other resections, removal of the astragalus should not be performed when the subject is affected with pulmonary tuberculosis, or is very old, or when the lesions are very extensive.—*Archiv Gén. de Méd.*, May, 1884.

Primary Tuberculosis of the Conjunctiva; Experimental Inoculations in the Anterior Chamber.—M. H. Parinaud says that tubercles of the

eye do not rarely occur as a primary lesion, especially in infants. If there is general infection existing, it is not shown by any positive symptoms in the lungs or other organs. Whether they develop spontaneously in man, or are the product of experimental inoculations in animals, tubercles of the conjunctiva are especially interesting, because they can be easily recognized, and in many cases we can follow out the characteristic evolution of the granulation.

Parinaud gives a detailed account of some experimental inoculations made in 1883. He introduced, through a wound made in the corneæ, into the anterior chamber of the eyes of a rabbit, the scrapings from an ulcer. In the right eye, a small fibrinous clot was enclosed in the wound. Three other rabbits, not inoculated, were placed in the same conditions of nourishment and hygiene. On the third day, there was intense ophthalmia of both eyes, characterized by hypopyon, diffuse cloudiness of the cornea, iritis, and injection of the globe. There was complete blindness. Parinaud believed the eyes lost. On the eighth day there was great amelioration of the inflammation. On the tenth day the hypopyon, which had occupied more than a third of the anterior chambers, had been in great part absorbed. The cornea of the left eye had recovered its transparency, save at the lower part and at the seat of the wound. The iris was easily examined, the pupil was dilated, and there were no adhesions. Vision seemed to be good. In the right eye the pupil was completely obstructed. On the twelfth day, there was a point of very limited vascularity running off from the pupillary border. On the twentieth day there were, at this point, two small, grayish granulations, which protruded from the border of the pupil. On the thirtieth day, new granulations appeared around the first, and became fused with them; others appeared at different points of the iris, the vascularity of which was increased.

At the seat of the inoculation-wound, there was a circumscribed yellow projection, upon which two small spots had the appearance of tubercles developing in the cornea. Lower down, at the situation of the hypopyon, where there were several whitish exudations, there was the same modification of the cornea. There was a little parenchymatous vascularity of the membrane. On the thirty-fifth day, the granulations of the iris had become yellowish, and were so fused together as to form an irregular caseous tract along the pupillary border. On the forty-fifth day, the cornea was opaque, and the iris could not be examined. The globe was vascular, and a little soft to the touch. The two corneal projections were larger, and formed two yellowish nodules. The cornea was infiltrated to the conjunctival edges. The lesions in the right eye were almost identical. The animal was completely blind, ate less, and lost strength. It was killed on the fifty-eighth day.

The autopsy showed the lungs filled with tubercles in different stages of evolution, from the grayish granulation up to tubercles as large as a small lentil, some of which were already caseous. These tubercles, very apparent to the naked eye, numbered about fifty; but under a glass, a great many transparent granulations were seen. There was no diffuse inflammation of the lung, the tissue of which, though everywhere injected with granulations, still preserved its elasticity. There were no appreciable granulations in other organs. On examining one of the eyes, it was found that the tubercles of the iris were much less apparent than during life, when the cornea was transparent. There was a yellowish, fibrinous exudation at the lower part of the anterior chamber, adherent to the cornea and iris. The two nodules of the cornea were formed by an opaque thickening of this membrane. One, situated on the sclero-corneal limb, involved the cornea, the conjunctiva, and the thickened episcleral tissue. The inoculating material had been carefully examined by MM. Marie and Vignal, and no bacilli discovered.—*Gazette Hebdom.*, June 13, 1884.

COMPLETE RUPTURE OF THE UTERUS; BIFID UTERUS.—M. L. SECHEYRON reports an interesting case of rupture of a bifid uterus. The patient was twenty-two years of age, and had always been in good health. At her first and normal pregnancy she was easily delivered. About three years afterwards she became pregnant a second time. In the eighth month she fell, and in trying to recover herself she felt a tearing sensation in the right flank, and immediately there was intense pain at this spot. After resting for a few moments she took a walk. The pain persisted for two days, when labor came on. It was then found that the fœtus had escaped, through a rent in the uterus, into the peritoneal cavity. The operator's (M. Bar) hand was passed through the rent and the child seized and brought out through the vagina. M. Bar then washed out the peritoneal cavity with a five per cent. solution of carbolic acid.

After the operation the patient was in a state of collapse, the pulse being 125 and thready, but she soon rallied, and for several days there was some hope that she might recover; she died, however, on the twelfth day.

The autopsy showed the presence of the usual adhesions and other appearances which were to be expected under the circumstances. The uterus was found to be bilobed. The left lobe, as large as the fist, had its axis inclined to the right, and from before backwards. The right lobe was less prominent, and occupied a plane posterior to that of the left, the external border of which appeared to have undergone a slight movement of rotation to the right, and from behind forwards. The right lobe was partly caught by a vesico-rectal peritoneal loop which terminated anteriorly at the posterior vesical wall, where its fasciæ seemed to spread out under the peritoneal covering of the bladder. Posteriorly it arose from the right side of the meso-rectum, near the median line. Each uterine lobe had a round ligament and a Fallopian tube. The cervix was sufficiently dilated to admit the index finger, which passed along a canal about two inches long and then came to the orifice of the rupture, situated between the two lobes and on a level with their junction. The cervix was split up to the point of rupture, and the left lobe opened toward the median line. The rupture was at the internal and lower part of the left lobe, the right not being involved. In fact, on the right the rupture seemed to terminate at the level of the vesico-rectal band. There was only one cervix, and between the rupture and the superior limit of the cervix there was a portion common to both lobes. —*Annales de Gynécol.*, June, 1884.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, JULY 19, 1884.

THE CHOLERA.

THE progress of cholera during the past week has been such as to warrant the belief that it will spread throughout Europe during the next thirty days, and may reach our shores at any time. Its progress can be arrested only by the most watchful care on the part of our quarantine officers—for this disease has *always reached our shores by ships*. Scrupulous cleanliness on board ship, isolation of all suspicious cases, absolute destruction of the fomites of those infected, and special care that the water supply is not contaminated (boiling it before use if there is any suspicion of its being impure), would add greatly to securing the healthfulness of ships; while municipal cleanliness persistently and systematically carried out, would leave no nidus for the disease to gain a foothold, even should it reach our shores.

Protective measures have been instituted by nearly all the transcontinental powers, and a general feeling of alarm seems to pervade the larger cities which are in the line of the pestilential march. In Marseilles, where the disease is now raging, the excitement is represented as being intense, and the Workingmen's Commission, referring to the plan of depopulating the city, which leaves the poorer classes without employment, have issued a red placard with the words: "The action of the municipality has left us nothing but suicide or a hideous death from hunger or epidemic." It is stated that over 120,000 people have fled from Marseilles within the last ten days.

Our Government has cabled its consular officers at London, Liverpool, Marseilles, Havre, Bordeaux, Bremen, and Hamburg, to immediately appoint sanitary inspectors, whose duty it shall be to thoroughly inspect all vessels, merchandise, passengers, and crews, bound for United States ports, and to refuse clean bills of health in all cases except where such inspectors certify that the vessels are clearly entitled to them. The consuls are further directed to report by cable any vessel bound to the United States about which any suspicion of disease exists, in order that our local health officers may have timely warning of approaching danger, and be prepared to meet it.

TRAUMATIC CEPHALHYDROCELE.

IN an exhaustive paper, read before the American Surgical Association, and published in the *American Journal of the Medical Sciences* for July, DR. P. S. CONNER has collated twenty-two cases, including two of his own, of subfascial accumulation of cerebrospinal fluid, of which nineteen were connected with and consequent upon simple fracture of the vault of the skull, and in three there had originally been a communicating wound of the scalp which had closed, two of these being cases of gunshot injury, while in the third the skull had been trephined.

The lesion has heretofore invariably occurred in young subjects, all, with one exception, in which the age was thirteen years, being three years and under, a fact which may be explained by the great elasticity of the skull in early life, permitting marked depression and fissuring of the vault without associated wound of the scalp, and by the more intimate connection of the membranes and skull in children than in youths and adults.

The diagnosis is not always easy when pulsation is absent, as it was in more than one-half of the cases, since, under these circumstances, the fluidity of the contents of the swelling and the thinness of the percussion-wave will excite the suspicion of a hæmatoma or a deep-seated abscess. The diagnosis, however, is clear when there is evident pulsation synchronous with the heart-beat; when there is increased fulness upon crying or holding the breath; when, upon pressure, a diminution in volume is readily effected, with or without resulting symptoms of cerebral irritation; and when the scalp is normal in color, and, it may be, translucent.

That the prognosis is bad is indicated by the fact that of the eighteen cases due to simple fracture, in which the result is known, nine died, and of the three in which the fracture was originally compound, one perished. In two of the fatal cases death was attributable to the treatment employed—incision and seton. Of the eleven recoveries, two exhibited a morbid mental condition.

Operative interference should be restricted to the removal by aspiration of a limited amount of fluid, but only when severe pressure symptoms have manifested themselves. In three of the recoveries an operation was not practised.

At the recent meeting of the German Surgical Association, the proceedings of which are recorded in the *Beilage zum Centralblatt für Chirurgie*, No. 23, VON WINIWARTER exhibited a boy, thirteen years of age, in whom a remote effect of the lesion under consideration, produced by permanent pressure, was well shown. When six months of age, the infant sustained a simple fissure of the right parietal bone, with the development, in a few days, of a characteristic cephalhydrocele, which was treated by compression, but which grew in proportion to the increase in the volume of the skull, until, finally, under the influence of the remedial agent, the bones were absorbed, leaving a defect, or loss of substance, five inches and a half in its long diameter, and two inches and three-eighths in its short diameter. The collection of fluid had, however, for some inexplicable reason, disappeared, and the defect was covered by normal skin; but that there still remained a loss of substance of the meninges was shown by the accumulation of fluid under the integuments when the patient was recumbent.

In the discussion which followed the reading of this paper, it may be stated that von Bergmann referred to a case reported by him at a former Congress, so that there are at present at least twenty-four examples of traumatic cephalhydrocele on record.

In his conclusions as to the treatment of this lesion Dr. Conner states that firm pressure will almost certainly produce or increase the symptoms of intracranial irritation; and the case of von Winiwarter shows that it exposes the patient to the danger of widening the original fissure, and ultimately inducing absorption of its edges, until a large defect results.

SUICIDE, AND ITS PREVENTION.

No one can read the daily papers without being struck with the present frequency of suicide. True, this is the season of the year when suicide occurs most frequently; and the recent great shrinkage in values, bringing financial ruin to thousands, has led some who, thinking themselves rich, and have not been able or willing to bear the losses which have brought them to poverty, to seek escape from this world. Both the season and financial reverses being recognized factors in the occurrence of suicide, time and active cause are favorable to this increase in the number of those who die by their own hand.

Another fact, which must be obvious to all who read these tragedies, is that in the great majority of cases those who thus die are men. They who have the more physical, and sometimes claim the greater intellectual strength, seem less able to bear up under life's ills, and, more readily, seek refuge in death. This difference in the sex of suicides is in part owing to woman's conscience being more active, and to her religious sentiment being stronger, for it would be foolish to claim that she suffers less in mind or heart or body, than man does.

Whether cases of suicide are only apparently more frequent now than a few years ago, it is certain that more occur in one week in the United States than can be found in the history of the Hebrew people during four thousand years. This seems like a sad commentary upon a civilization which is doing much for the benefit of man, and for the improvement of society. It becomes the philanthropist and the political economist to inquire whether there are not evils which may be removed, so that life, if not rendered more desirable, may at least be made more tolerable. These countless tragedies are a protest against life, a cry of sad despair; life is not worth living, is the acted declaration of every man or woman who perishes by his or her own hand. Cannot the value and the sacredness of life be increased, so that these horrors which often carry unutterable sorrow to many hearts may be diminished? Apart from any influence exerted by a wise political economy, and a generous philanthropy, by which the value of life will be enhanced, the estimate which is set upon it is closely connected with systems of philosophy, and with religion. To discuss these topics, however, would require too much space, and might suggest controversy.

What other means may be sought to prevent this great evil? Ptolemy made short work with the teaching of the Cyrenic philosopher, Hegesias, and thus arrested an epidemic of suicide; but Ptolemy does not govern in this country, and there is no arbitrary power to decide that the works of pessimistic philosophy which makes a cosmic suicide the goal of the race, should not be published. Esquirol, and several alienists since him, have expressed the desire that newspapers should be forbidden to publish cases of suicide, because these recitals may lead some readers to kill themselves. But in this country such legislation is impossible.

The chief means of prevention lying in the hands of physicians, is the timely recognition of the danger in a given case, and immediately putting the patient where self-destruction will be impossible. Thus many a suicide could and would be prevented. One of our great professional shortcomings is in not recognizing the premonitory symptoms of these acts, the heralds of these tragedies. In too many cases the symptoms are plain and the heralds give no uncertain sound, after the event. We do not know that this evil would be avoided by the plan suggested by Dr. Holmes in his last Harvard address, nor do we know that the plan is practicable, but our own observation may be quickened by reading it: "I have often wished," says our wise teacher, "that disease could be hunted by its professional antago-

nists in couples—a doctor and a doctor's quick-witted wife making a visit and attacking the patient—I mean the patient's malady, of course, with their united capacities. For I am quite sure that there is a natural clairvoyance in a woman which would make her as much the superior of man in some particulars of diagnosis as she certainly is in distinguishing shades of color. Many a suicide would have been prevented, if the doctor's wife had visited the victim the day before it happened. She would have seen in the merchant's face his impending bankruptcy, while her stupid husband was prescribing for his dyspepsia and indorsing his note; she would recognize the love-lorn maiden by an ill-adjusted ribbon, a line in the features, a droop in the attitude, a tone in the voice, which mean nothing to him, and so the brook must be dragged to-morrow."

One fact should be present in the physician's mind: Any one who purposes self-destruction is most probably suffering from physical disease, and in every case the accomplishment of the purpose should be rendered impossible either by immediate committal to an asylum for the insane, or by his being kept every minute under a qualified guard.

While referring to the subject of suicide, we wish to call attention to some recent interesting observations of Voisin, in which he mentions the most important signs of suicidal insanity, and localizes the affection. He states that these patients ordinarily complain of violent bregmatic and sincipital pain, and the temperature of the parts where this pain is felt is notably increased. Clinical histories and post-mortem examinations have led him to the conclusion that the ideas of suicide in the insane are connected with functional disorders and lesions seated in the most internal of the ascending frontal and parietal cerebral convolutions.

Another noteworthy point in connection with the subject of suicide, is the partiality men have for destroying their lives by firearms, and the unfortunate facility with which these implements of destruction can be procured. Women who commit suicide use a pistol rarely, only one to fourteen men, for this purpose; they will hang, drown, take poison, stifle themselves with carbonic acid, or throw themselves over a precipice, rather than put an end to their lives by a bullet.

Among the most important means to prevent suicide is work. The man who is out of employment, who has been discharged from his place, or met with such financial reverses that his business is lost, is occupied brooding over his misfortunes until they grow in size and blackness, and death seems to him better than life. Give that man work for every minute of his waking hours, and he will have no time to think about destroying his life. Better work for nothing than to be idle. Work is the law, the fountain, the guardian, the reward of life.

FEMALE PHARMACISTS.

Louisville has the honor of having opened the first school in this country for the education of women in pharmacy, and so far the institution has succeeded. The annual commencement of this college recently occurred, and a part of the exercises of the occasion was an address by Dr. Yandell, which was plain, practical, wise, and suggestive. In it he pleasantly stated that, among other reasons for women being fitted to prepare medicines, they took medicine and gave it better than men, had more faith in it, and needed or thought they needed more than men.

One important truth among those which Dr. Yandell presented to the "girl graduates," was that, entering into competition with men, they must expect just the treatment men give their fellows: "You have chosen to align yourselves with man. You have become his competitor for bread, his rival in work; look for no other treatment than he gives his fellows. The lines of commerce are merciless, and true banking knows no friends." This truth is of great importance, and we sometimes think is not fully appreciated by all those who enter this contest, whether in the professions or trades hitherto occupied exclusively by men.

Undoubtedly woman possesses qualities which peculiarly adapt her to pharmacy, and her success she alone must determine; it is well that the experiment is being tried, for the just tendency of the time is to demand more and better paid work for women.

BIDDING FOR STUDENTS.

We have had our attention called a number of times to a practice of a Baltimore medical college, of sending out with its catalogue a circular inviting the physicians receiving it, to recommend young men for admission on certain "special privilege" terms, which are set forth in the catalogue. A few days ago the catalogue of the school was received by us in the regular way, and between its pages we found a postal card having upon it the address of the Dean, and containing the printed form above referred to, with a line left for the insertion of the name of the student so recommended. On examining the accompanying catalogue, we find that the "privileged student" is admitted for half the usual fees, which, without this reduction, are less than those of first-class medical schools.

Such unlimited bidding for students can only have the effect of degrading medical education and lowering the institution which adopts it in the eyes of the better class of the profession—the very ones whose respect it should seek to win. And we would say for the benefit of the school concerned, that all who have commented on the matter to us have done so

with a view to express decided disapprobation and contempt for the practice, of which the intent is so obvious.

The country is overrun with half-educated doctors who are a reproach to the profession and a danger to the community, and the conditions of admission to the profession should be made more, rather than less stringent. We have already stated in these columns how this can be done without excluding the properly qualified indigent student. Opportunities for free instruction should exist, but they should be limited, and scholarships awarded only to those who pass best in a stringent competitive examination.

REVIEWS.

ATLAS OF MICRO-PHOTOGRAPHS OF PATHOLOGICAL AND ANATOMICAL PREPARATIONS. Photographed and demonstrated by DR. RUDOLPH MENGER. Quarto, pp. about 40. Plates lxvii. San Antonio, Texas, 1884.

As a collection of photographs of pathological subjects, we regret to be compelled to say that this book is a lamentable failure, since most of the genuine productions might be readily mistaken for a series of views of the planet Jupiter, with his irregularly clouded surface, as seen through the telescope, or for veritable sun-pictures, exhibiting the dark spots upon our central orb which have so long puzzled astronomers.

Yet, as photographs of pen-and-ink sketches, many evince a remarkable talent, and one which Dr. Menger should spare no pains to cultivate. Plate xli. shows in its upper half a beautiful picture of one of the planets, and in its lower semicircle an exquisite drawing of cancer of the fundus uteri. But the most remarkable of the series is Plate xix., purporting to be a photograph of adenoma of the kidney, in which, under a magnifying glass, the borders of the cells and the connective-tissue fibres exhibit—as do those of Plate xli.—the same notches and occasionally retouched outlines which characterize the marginal reference letters and their accompanying braces.

To the working microscopist this work is almost as great a curiosity as the book entitled *English as She is Spoke* is to a philosophical linguist; so that we venture to predict for the volume an eager, though perhaps limited demand.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, June 18, 1884.

THE PRESIDENT, WM. M. WELCH, M.D., IN THE CHAIR.

DR. JOHN S. MILLER presented a paper entitled

ETHERIZATION BY THE RECTUM; REPORT OF FOUR CASES BY YVERSEN'S METHOD.

He said, I desire to report four cases of etherization by the rectum, a method of producing anæsthesia first suggested by Dr. Axel Yversen, of Copenhagen.

These cases were in my recent practice; and to Drs. Louis Jurist and A. B. Hirsh, I am indebted for assistance rendered, and for many of the observations made. In two of these cases the mucous membrane of the bowel was prepared for its respiratory function, as it ought to have been in all, by a restriction of diet and the use of purgatives. No preliminary hypodermics were used. The method of administering the ether was simple. A definite quantity was placed in a bottle (only partially filling it), was vaporized by a water-bath at 120°, and the vapor conducted to the rectum by a rubber tube, terminating in a recurrent catheter, the free or recurrent end being closed by pressure of the thumb during the inflation of the bowel; the expiratory act was performed by removing this pressure, and removing the water-bath.

The first case was one for minor operation, demanding only primary anæsthesia. This patient had not been prepared, and sufficient precaution was not taken against the introduction of ether vapor in too great a quantity, and of liquid ether, by an overboiling in the apparatus. Almost immediately he complained of burning and tenesmus, the abdomen became promptly and greatly distended, and there were colicky pains. In about one minute he noted the taste of ether. A portion of the vapor was allowed to escape, and no more was given. The pain ceased, intoxication soon began, and in six minutes he was sufficiently anæsthetized for operation. The pulse was full, and respiration was easy. Two minutes later he returned to consciousness, but seemed dazed. The struggling had been trifling. There was no vomiting, and no diarrhœa followed. One ounce of ether was used.

The second patient was an adult male, from whom I removed an exostosis of the vomer—an operation requiring full anæsthesia. In this case a sufficient laxative had been given the previous night. Two hours before the operation he had been allowed an ordinary breakfast. This patient, too, experienced a prompt burning and discomfort in the rectum, but at no time great, and soon ceasing. Ether was tasted in about two minutes, and noted on the breath. The abdomen seemed distended and some cramp-like pains were experienced. A considerable amount of vapor was then allowed to escape—with instant relief. After waiting two minutes without the development of further phenomena, a somewhat less amount of vapor was introduced, and (the catheter being withdrawn) was left for gradual absorption. The stage of excitement was short, marked by a pleasant delirium, and without motor activity. Full anæsthesia was obtained in eleven minutes from the first introduction of the ether vapor, and was perfectly maintained during the eight minutes of operation. Escape of the residual vapor was secured by a gentle kneading of the abdomen, and separation of the nates. The posterior nares not having been plugged, considerable blood regurgitated from the stomach after operation. This vomiting cannot, with any certainty, be attributed to the ether. No diarrhœa followed. An ounce and a half of the anæsthetic was used.

The third patient, also an adult, robust male, was subjected to acupressure of the internal saphenous vein, with destruction by means of Vienna paste of several neighboring vessels—an operation also requiring full anæsthesia. He had received a laxative the day before, and an enema on the morning of operation, and had taken a moderate breakfast. The sensation of warmth

and tenesmus was immediate, but soon ceased. The abdomen became distended, and he complained of epigastric pain. A partial escape of vapor was permitted, and he had instant relief. A few minutes later the bowel was again inflated, and the tube withdrawn. Enough vapor remained after withdrawing the tube to produce complete anæsthesia in a total of fifteen minutes, and no further introduction was required to maintain it. There had been almost no stage of excitation, and no other phenomena than an immoderate laughing. He recovered promptly. No vomiting or diarrhœa followed. A little less than two ounces of ether were used.

The fourth case was that of a medical gentleman in good health, whose love of science led him to volunteer a passive part in these experiments. This time the bowel had not been prepared, although an ordinary movement had taken place five hours previously. On introducing the vapor, there were slight burning and tenesmus, but no cramps. Intoxication was soon induced, and the doctor seemed most of all to enjoy the proceedings. Pulse and respiration were normal. A lively peristalsis now put an end to this mode of administration, and terminated the experiment.

The only reason for quoting this case is the evidence it furnishes for the necessity of preparing the bowel—a necessity which excludes this method of etherization from our resources in accident and emergency cases.

This case completes the four, and I have had no other opportunities for observation.

Some question having arisen as to whether the vapor really does pass the ileo-cæcal valve, I deemed this a subject for legitimate vivisection, and, etherizing a cat per rectum, opened the abdominal cavity, and noted that the small intestine was as greatly distended as the large.

In this method of etherization, the most obvious advantages are as follows:

1. Dyspnœa is avoided, and the patient is saved from the anxiety due to a sense of impending suffocation.

2. There is avoided the danger of simultaneous irritation of the superior laryngeal and pneumogastric nerves at the periphery—these irritations neutralizing each other in the respiratory centre, and suspending respiration entirely.

3. The danger of asphyxia is lessened—the patient not being drowned in his own mucus, and the integrity of the pulmonary mucus membrane as an organ of gas exchange is preserved. Of course, some vapor finds itself in the lungs, and acts there as a local irritant—elimination being by that channel. But the quantity is not great, and does not constitute a source of danger. In the cases reported, the increase in secretion was too trifling for discovery.

4. The stage of excitation is therefore not prolonged by the struggles for breath. In general, it may be said that the delirium of any alcoholic intoxication is a pleasant and good-natured one, unless the patient is crossed—as he certainly feels himself to be when a wet towel is pressed over his face.

5. Nourishment may be taken before operation to sustain the powers of life, and lessen the dangers from shock.

6. Return to consciousness is prompt—this stage not being prolonged by carbonic acid poisoning.

7. The anæsthetic seems as readily suspended as by the ordinary method—the bowel being promptly emptied by gentle massage.

8. Economy in ether is an advantage hardly to be mentioned with more important considerations.

The more obvious disadvantages are:

1. The exposure of person required—the abdomen being necessarily under observation, even if the catheter be inserted under cover.

2. More judgment and experience are required in the administration, than by the ordinary method—overboiling in the apparatus, and too much distention, being both painful and highly dangerous. The warning to cease is sudden, and must be immediately obeyed.

3. Just as the other mode is inconvenient in oral surgery, so in perineal operations is the apparatus needed for this method, in the way.

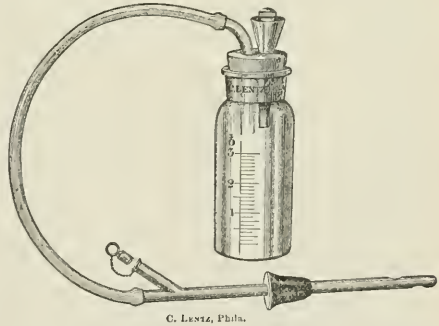
4. In abdominal surgery, or if there be marked intestinal lesion, this mode is contra-indicated.

5. The inapplicability in cases of accident and emergency, when time cannot be allowed to prepare the bowel, has already been mentioned.

6. Diarrhœa has been noted in seven out of the thirty-seven cases on record, though in none of mine.

I believe this sequel is due to preëxisting intestinal lesion, to the lack of preparation, to a too great distention of the bowel, or to the accidental introduction of ether in liquid form. Furthermore, my method has differed from that of other experimenters in this respect, that instead of allowing the vapor to remain indefinitely, I secured a constant change by using a recurrent catheter, and introducing a certain quantity, or permitting it to escape, as indicated.

Other points of advantage and disadvantage may occur in later experience, and to other observers, and new dangers may be discovered. But I am convinced that this method is worthy of further trial, and will find its place in surgery, fulfilling its own, though not *all*, indications. Like all else in therapeutics, it must pass through the stages of bungling use, condemnation, and revival.



Dr. Miller then exhibited a form of apparatus which he had had made by Charles Lentz & Sons, No. 27 South Tenth Street, for this purpose. It consists simply of a water-bath, a graduated bottle provided with a funnel and valve for pouring in the ether, and a supply-pipe

for conducting the vapor to the rectum. This tube terminated in a straight recurrent catheter, the exhaust-channel of which is controlled by a valve. The catheter is furthermore provided with a movable collar for pressure against the anus—it having been found that the vapor tends to escape by the side of the tube.

THE NEW YORK ACADEMY OF MEDICINE.

Section of Obstetrics and Diseases of Women and Children.

Stated Meeting, April 24, 1884.

Alexander S. Hunter, M.D., in the Chair.

Dr. A. Jacobi read a paper on

THE MEDICINAL TREATMENT OF MEMBRANOUS CROUP.

He commenced by saying that in 1868 he formulated the indications for tracheotomy in croup in the following words: "There ought to be no contraindication when the prominent symptom is dyspnœa and suffocation. I cannot imagine any complication of croup that would prevent me from opening the trachea when the child is dying of suffocation. This is so plain to my understanding that I should consider it more a cruelty to refuse tracheotomy when I know beforehand that the child was surely going to die. Whoever has seen children die of croup, fully conscious, gasping, raving for air until they are slowly strangled in your arms, under your eyes, will at least bless a proceeding, the consequence of which will in most cases be an easier death. Nor do I acknowledge that tender age, the age under two years, ought to be held as a contraindication to the performance of the operation." Such were the principles, he said, on which the operation of tracheotomy was based, and he would as soon think of refusing to cut down a man who was hanging by a rope about his neck, even though he might be the subject of tuberculosis or carcinoma, as of refusing to perform it in any case in which the indications mentioned were present. Monté had collected 12,736 cases of croup with general diphtheria, in which no less than 3409 were saved by tracheotomy.

At the time that he read his paper on the pathology and treatment of croup before the Medical Society of the County of New York, in 1868, he was accused of cutting altogether too many throats; as up to that time tracheotomy was comparatively rarely resorted to, in New York, except by Drs. Roth, Voss, and Krackowizer. The latter up to that time had operated in fifty-six cases, all of which, with one exception, were in the city. Since then, however, the drift of medical opinion had gradually changed. The extent of this change had been very great, and at the recent discussion of the operation in the Section he had been gratified to see that eminent physicians who had been especially identified with the medical treatment of croup had advocated it so freely. Every practitioner of medicine, he thought, ought to be prepared to perform the operation at any moment, and he believed that there were now hundreds of medical men in New York who were ready and anxious to do it whenever an opportunity presented itself. For himself, he had now performed tracheotomy four hundred times or more, while he had witnessed it in several hundred other cases.

When such, therefore, were his sentiments in regard to tracheotomy, and when such had been his experience with it, he would not be accused, in preparing the present paper, of advocating medicinal treatment to the exclusion of operative interference. Dr. Jacobi then gave a sketch of two cases of croup, in one of which the child was a little over, and in the other a little less than, two years old, which had been under his care at the Mount Sinai Hospital. The patients were placed under a tent, the temperature of which was kept at 70°, and which was constantly filled with steam and the vapor of turpentine. Neither of the cases was of great severity, and neither was of septic character, and they were treated with one-thirtieth grain doses of pilocarpine muriate, in accordance with the method of Guttemann. In regard to the efficiency of this drug, he had not modified the opinion which he had expressed at the meeting of the American Medical Association in 1881. This remedy had been recommended as a specific, but the real efficacy of such new agents was to be tried, not in moderate cases, which would probably recover without any treatment, but in severe ones, and for that reason he had first used pilocarpine in severe cases—in cases of nasal diphtheria and in the septic form of pharyngeal and laryngeal diphtheria, with or without glandular swelling. In not a single instance had he seen the slightest favorable effect; but, on the contrary, he felt sure, from two or three observations, that the fatal termination was certainly accelerated by the influence of the remedy. So far as we know, pilocarpine, either directly or indirectly (by producing vomiting), debilitated the heart's action, and when the pulse was frequent and small, the action of the heart feeble, and the tendency to collapse prevalent, as in many cases of serious diphtheritic affection, the agent could do no good whatever. Of the cases referred to at the Mount Sinai Hospital, one recovered under the treatment mentioned, and in the other the pilocarpine had to be withdrawn in two days, on account of its severe effects, notwithstanding the fact that alcohol was administered freely to counteract its debilitating influence. This child's final recovery seemed to be due, in the first place, to the macerating effect of the pilocarpine upon the pseudo-membranes, and, secondly, to the timely withdrawal of the remedy. Another child, three years of age, recovered with a fair amount of strength after taking pilocarpine for four days. In Dr. Jacobi's opinion, it was a powerful remedy, useful under certain conditions, but one the depressing effects of which it was necessary to watch with great care and counteract.

In numerous cases he had employed steam inhalations. In regard to the efficacy of this means of treatment, he had not changed the views that he had expressed in his treatise on diphtheria, published in 1880. It is true that pseudo-membranes, like everything else, became softened by the warm vapors. It was also probable that steam increased the secretion of the mucous glands, and thereby possibly loosened the overlying membranes, and favored their removal; but it was not to be forgotten that it also softened the healthy tissues, and that this change in character enabled the poison, whatever its nature, to penetrate more deeply into them. The results from the inhalation of

steam in diphtheria of the larynx had not always been pleasant. He had repeatedly had the joy of seeing children with croup become less cyanotic after their removal from an atmosphere of vapor, and he could readily see that pure atmospheric air might be more agreeable and wholesome to a child with stenosis of the larynx than an atmosphere laden with steam. Steam for the purpose of softening the tissues, and of provoking the secretion of mucus and suppuration, had been used to a very considerable extent, both in this country and in England; and he had seen cases of fibrous bronchitis getting well, when he had every reason to attribute the recovery to the persistent use of this agent. In one case, he had shut up a baby in a small bath-room with one window, and let the hot water run continuously for days, so as to produce a constant fog, and make every person in it dripping. The result was highly gratifying, as the baby got well; and so did another, whom he had the good fortune to benefit by his experience in that case. Individualizing was a great art, but in regard to steam therapeutics it was not so difficult. The object of the steam was to soften, but principally to increase the secretion from the mucous membrane, and thereby throw off the superjacent membrane. This could be done to advantage only when there was a natural tendency to it, and that was where there were a great many muciparous follicles under a cylindrical or fimbriated epithelium. This was the condition in part of the pharynx, but not in the tonsils, in a small portion of the larynx, in the trachea and bronchi, but not in the vocal cords. Wherever there was pavement epithelium on the normal surface, and where the membrane was embedded into the tissue, steam could hardly be expected to do good. In the other cases it would. Thus, the locality of the diphtheritic process determined to a great extent whether steam was indicated or not. If it were used, however, the necessity of a full supply of atmospheric air was not to be disregarded. Steam with an overheated room, and without pure air, was liable to be as injurious as steam in pure air was beneficial in a number of cases. The object for which steam was inhaled was to soften and remove membranes. When that could be accomplished without reducing the required amount of oxygen, all was well; but when respiration was annoyed or interfered with, the contraindication to steam was as clear as the indication in more favorable cases.

Turpentine had of late years been highly recommended in croup and diphtheria, and he could only repeat his former assertions in regard to its employment. For years he had been in the habit of using turpentine, either the oil or the rectified spirits, as an inhalation in bad cases of pneumonia, in which hepatization was very extensive, and expectoration and resolution did not commence, with very good result in children and adults, and the method he had employed was equally applicable in croup. The vapors of turpentine were so volatile and penetrating that the usual method of inhaling from an apparatus appeared to him superfluous; so that he allowed the patient to remain in bed, while water was kept boiling constantly on the stove or over an alcohol lamp or gas-jet. A tablespoonful, more or less, of rectified spirits or oil of turpentine, was poured on the water, care being taken that none of it was spilled in the fire; and thus the room was constantly filled with a penetrating odor of turpentine, which was not at all disagreeable, even when in great concentration. The effects were very satisfactory. When circumstances allowed or required it, he was in the habit of raising a tent over the bed, large enough not to give inconvenience to the patient, and to admit either the whole apparatus or the tube containing the mixed vapor of water and turpentine. This plan he followed in a case of laryngeal diphtheria in a little girl, two years old, in the children's service of the Mount Sinai Hospital. The baby was in a room of her own, with a nurse, and a tent was raised over the bed. Four days and nights she was exposed to the water and turpentine treatment, awake or asleep; and the presence of the nurse under the tent with her was insisted upon by the patient whenever she was awake. The case was not allowed to become, or, at all events was not a very serious one, but was serious enough to be diagnosticable, to produce hoarseness, aphonia, and dyspnœa, and to render the perception of pulmonary murmurs impossible, though there never was cyanosis, with the exception of a slight hue on the upper lip.

Dr. Jacobi then said that he would now select one topic for discussion which seemed to him of considerable importance, but was not a new one, and that was the use of mercury; after which he proceeded to give an exhaustive *résumé* of the opinions of various authors, for and against, up to the present day. He first mentioned Dr. Samuel Bard, who, in 1771, recommended the administration of from three to five grains of calomel a day, and then Dr. Rush, who also advocated its use in his *Medical Inquiries*. Among the others to whom he referred were the following: Bretonneau used mercury not only internally, but by inunction in the form of the ointment, and with good effect. Guersant favored it, but Trousseau was wholly opposed to its employment, and on account of the weight of his authority it sank into almost entire disuse for a considerable time in France. After alluding to a number of German and English writers, who for the most part favored its use, he quoted from Dr. George B. Wood, of Philadelphia (*Practice of Medicine*), 1847, Bourgeois, 1850, Barum, 1861, and Bartles, 1867. The latter reported forty-one cases of croup, five of which recovered under the use of mercurial inunction. After long experience with the drug, however, he discarded it. Oppolzer used calomel and iodide of potassium; Senator, calomel and antimony; and Rauchfuss, calomel with oxysulphuret of antimony, the ointment, and hypodermatic injections of the corrosive sublimate. Dr. Jacobi then alluded to the views which he himself had expressed in his work on diphtheria, in which he stated that in regard to the action of mercurial remedies he was no longer so sceptical as he had been a quarter of a century before, and admitted that the experience of many subsequent years had changed his opinion to a certain extent. He quoted as follows: "I also know that when the constitutional effect of mercury could be obtained speedily, cases of fibrinous tracheo-bronchitis got well in an unexpected manner. To accomplish that, it is necessary to give small doses very frequently. Calomel, grs. viij to xij, divided into thirty or forty doses, of which one is taken every half hour, is apt to yield a constitutional effect very soon. Such doses, with minute doses—$\frac{1}{60}$th grain or more—of tartar emetic, or ten or twenty times

that amount of oxysulphuret of antimony, have served me well in fibrinous tracheo-bronchitis. But the mucous membrane of the trachea and bronchi is more apt to submit to such liquefying and maccrating treatment than the vocal cords. The latter have no muciparous glands like the former, in which they are very copious. And while the tracheal membrane is apt to be thrown out of a tracheal incision at once, though of more recent date, the pseudo-membrane of the vocal cords takes from six days to sixteen or more for complete removal." He next went on to say that if ever mercury was expected to do any good in these cases of suffocation by membrane, it had to be made to act promptly. That is what the blue ointment did not do. In its place he recommended the oleate, of which ten or twelve drops might be rubbed into the skin, along the inside of the forearms or thighs, every hour or two hours. In place of, or in addition to this, repeated doses might be given, as recommended above, or hypodermatic injections of corrosive sublimate in a one-half or one per cent. solution of distilled water, four or five drops, from four to six times a day. Dr. Horatio C. Wood, in his *Therapeutics*, said that calomel was useful in severe laryngitis, and especially in the pseudo-membranous variety, when the type was sthenic; and no time should be lost in bringing the system under its influence. In whatever disease a mercurial was administered as an antiphlogistic, it should be given during the stage of exudation, and to facilitate the absorption of the newly organized lymph after it had ceased to be thrown out. In the majority of cases, mercury given for its constitutional effects should be combined with opium, to prevent its acting on the bowels. Calomel should not be used in adynamic inflammations, or where the exudation was serous rather than fibrous. In Reynolds's *System of Medicine*, mercurials were hardly mentioned in this connection. J. Lewis Smith, in his work on diseases of children, said that calomel, which had been largely prescribed in times gone by for its supposed "antiplastic" action, had been properly laid aside, and Roberts Bartholow, in his *Therapeutics*, expressed himself as very sceptical in regard to the utility of the remedy.

Erichson, of St. Petersburgh, was the first to recommend the cyanide of mercury, and he used it in patients from seven weeks to thirty years old; one-hundredth of a grain every hour being given to young children. In twenty-five cases of croup it was successful in all but three, in which the fatal result was due to complicating causes. In all, the diphtheritic process became extinct. Another writer reported only three deaths out of ninety-eight cases treated by the cyanide, but stated that the remedy had no effect if the larynx was already affected with stenosis. Schultz had used mercury hypodermatically with success, and employed the cyanide principally. Meigs and Pepper (*Diseases of Children*, sixth edition, pp. 100 and 101) said: "Calomel is the preparation almost always preferred, and many authors still recommend the administration of this remedy, in larger or smaller doses, in the earliest stage of the attack. During late years our increased dislike of the administration of mercury to children in large and frequently repeated doses, and the constant observation that even its free use does not appear to arrest the cause of true croup, or prevent the formation of membranous exudation, have led us to abandon entirely its employment in this disease."

It was evident, from the various authorities that had been quoted, Dr. Jacobi continued, that the difference of opinion in regard to the value of mercurials was very great; but one fact was noticeable, viz.: that, as a rule, the text-books, which were based on acknowledged facts only, were more or less unfavorable in their judgments, while the writers who spoke from their own personal experience generally appeared as the friends of the mercurial treatment. His own opinion, of 1880, had been somewhat still further modified in favor of mercury, especially the bichloride, and he had been particularly impressed with the statements made by Dr. William Pepper in his Address in Medicine at the meeting of the American Medical Association in 1881. In the course of this he said: "But I cannot omit a passing reference to the remarkable results that have recently been observed to follow the use of large doses of bichloride of mercury in diphtheria. The original paper that brought this subject to my notice was by Dr. G. A. Linn, of Washington County, and was published in the *Transactions of the Medical Society of Pennsylvania*. The extraordinary statements there made have been confirmed by the experiences, as yet unpublished, of several competent observers." Having then related a case which he saw in consultation with Dr. T. J. Yarrow, of Philadelphia, in which a child, five years old, apparently in *articulo mortis* from diphtheritic croup, was saved by doses of one-thirty-second of a grain of bichloride of mercury, given every second hour in solution in elixir of bismuth and pepsin, with two drops of tincture of nux vomica, he concluded his remarks on this subject as follows: "The extraordinary tolerance of such large doses of bichloride of mercury, and the rapid and progressive improvement from so desperate a state, make me regard this as one of the most remarkable cases I have ever witnessed, and will certainly induce me to give further trial to this remedy, given in the same manner, in cases of grave diphtheritic infection."

Dr. Jacobi then went on to say that, while he had of late met with a gratifying measure of success in the use of the mercurial treatment, he was not one of those who "had never lost a case." As to the preparations of mercury to be used, he thought it was best to use a very few, and to give them them a thorough trial, and none of them apparently offered the advantages of the bichloride. It was best to give it largely diluted, say about one part to three thousand of water (one grain to the quart), and, as an albuminate or a peptonate would be formed, gastric and intestinal disturbances would be avoided. Having spoken of the extraordinary power of the bichloride as a germicide, mentioning in figures, as determined by actual experiments, its great superiority to phenic acid, thymol, salicylate of sodium, carbolic acid, quinine, and other antiseptics, he referred to a paper on "The Treatment of Diphtheria and Croup by Large Doses of Bichloride of Mercury," recently read by Dr. William M. Thallon, of Brooklyn, before the Kings County Medical Society, and published in the *New York Medical Journal*, for April 12 and 19, 1884. In this, he reported ten successful cases, and in his remarks upon them said that it was very difficult, indeed, impossible, to draw a positive therapeutic con-

clusion from treatment used in sporadic cases only, and he, therefore, acknowledged that the value of the bichloride of mercury treatment would not be established until it had proved efficient to cope with a severe epidemic of diphtheria. Still, enough had been shown, he thought, to warrant the claim that this mode of treatment was well worthy of a more extended trial; and the hopelessness and confusion of all other methods are such as to make us eagerly resort to one which was so plausible as this, and one that already had so much clinical evidence in its favor. If the bichloride were used hypodermatically, Dr. Jacobi advised that chloride of sodium should be added to the solution injected.

After tracheotomy had been performed, care should be taken that the temperature of the room should not be too high—not much over 70°—and that the air should be kept moist; this could readily be done by means of an ordinary kettle, to the spout of which a tin cylinder was attached, so that the steam should not escape up the chimney. Gas-stoves were very injurious, however, and were never to be used for heating the water. If it were deemed advisable, the child could be placed under a tent, and steam, charged with the vapor of turpentine, as previously referred to, introduced by means of a tube. As before, however, it was of primary importance that oxygen should not be excluded. In a child suffering from descending diphtheria, who was in convulsions from poisoning by carbonic acid gas, he had been enabled to check the convulsions by the introduction of oxygen through the tube in the trachea. Moderate feeding and the use of stimulants were to be resorted to soon after the operation. As to the employment of internal treatment, whatever remedy the child had been taking before was still to be continued — no change being advised unless a change in the symptoms occurred. Broncho-pneumonia not infrequently set in within a few hours after tracheotomy. Where this complication ensued quinine by hypodermatic injection was advised, and the best preparation for the purpose was the carbimide. Salicylate of sodium and sulphate of strychnia (one-twenty-fifth of a grain every two hours till four or five doses had been taken) were also useful, and small doses of digitalis, promptly given, were recommended where the heart required it. Every case must be treated according to its special circumstances. Alcohol would undoubtedly be needed, and camphor might be of service. In cases of urgency, when collapse seemed imminent, Siberian milk was advised. In short, the disease was not to be treated in a routine way because of its name, but in accordance with the actual indications present in the special case presenting itself.

Dr. Jacobi stated his conclusions as follows:

1. The mercurial treatment o membranous croup was promising of good results.

2. The bichloride appeared to be the best preparation for this purpose.

3. The remedy should be given early and frequently repeated.

4. The bichloride should be well diluted (about 1 to 3000).

5. To babies about half a grain should be given in the twenty-four hours, and, as a rule, its administration could be kept up for many days, if necessary, without bad effects.

6. Stomatitis or salivation is very rarely observed, and gastro-intestinal disturbances are not frequent under its use.

7. If any unpleasant consequences result from the bichloride, inunction by the oleate of mercury is advised in its place.

8. If the treatment of the diphtheritic disease be undertaken in time croup may often be prevented, as this is believed to be due to descending pharyngeal diphtheria.

At the conclusion of his paper, Dr. Jacobi referred to three cases which he said he had selected out of a large number of others as samples to show the efficacy of the bichloride treatment. The first was that of a child two years of age, whom he had seen in consultation with Dr. E. J. Hogan. It commenced as a mild pharyngeal inflammation. In the evening the medical attendant left the patient in excellent condition, but was summoned at 3 A.M. to find that alarming dyspnœa had suddenly set in. Turpeth mineral was promptly given, and this produced partial relief, but also gave rise to profuse diarrhœa, which lasted for twenty-four hours. The next day the child was found to be steadily growing worse. The pulse was from 150 to 160, and the respirations from 50 to 66 to the minute, while there was epigastric and supra-sternal recession. Carbonate of ammonia was now given, but the condition of the child becoming more and more alarming, tracheotomy was advised and performed. No membrane had been detected in the throat or nose, but its presence was now revealed in the trachea. The wound was treated with a solution of bichloride of mercury (1 to 2000) and iodoform, while Dover's powder was given internally. After a time the patient began to suffer again from increasing obstruction, and Dr. Jacobi was called in consultation. By his advice one-thirty-second of a grain of bichloride of mercury was given every hour, and from this time on the recovery commenced. The remedy was discontinued on the third day, on account of the gastro-intestinal irritation which it occasioned. In this case the bichloride was commenced when the rapid formation of thick membranes was going on, and when there was every indication of approaching death; and Dr. Hogan remarked that his experience in it had been such that in any similar case he should feel that it would be a neglect of the patient to withhold this remedy.

The second case was one of croup, in a child of twenty-one months, occurring in the course of pharyngeal diphtheria. One-twentieth of a grain of bichloride of mercury was ordered every hour for three days, and the child recov ed. The third case was seen by Dr. Jacobi in consult on with Dr. T. Herring Burchard, who read the notes of it. An infant five months old suffered from a very bad attack of fibrous laryngo-tracheo-bronchitis, and for a number of days in succession it was given one-fiftieth of a grain of bichloride of mercury every hour. At one time the child became markedly cyanosed, on account of the accumulation of mucus in the throat, and was supposed to be dying; but by placing it in an inverted position the mucus was dislodged. Towards the close of the attack inunction by the oleate of mercury was substituted for the bichloride for a time. A good recovery was made. When Dr. Burchard had finished the history of his case, Dr. Jacobi made a few final remarks, in the course of which he stated that in

the last fourteen years he had never had so many recoveries in croup, either before or after the operation of tracheotomy, as during the last year, when he had extensively used the bichloride of mercury.

DR. W. E. FOREST stated that two years ago he treated a case of croup, in a child seven years of age, which continued to grow worse until the end of four days, when there was complete aphonia, and Dr. Jacobi was called in. He advised one-twentieth of a grain of bichloride of mercury every hour; but three doses of the medicine brought on such violent tenesmus that the dose was reduced to one-fiftieth of a grain, after which there was no further trouble of this kind, and the child made a good recovery from the attack. Since that time he had used the bichloride extensively, and a very large number of his cases had recovered. It was certainly a fact that in his treatment of croup when the trouble was not so much of the diphtheritic variety as of an inflammatory type (not commencing first in the pharynx), the bichloride (in doses of one-fiftieth grain) had acted surprisingly well. In addition, he was in the habit of using inhalations of steam from Codman and Shurtleff's atomizer, in preference to charging the air of the whole room with vapor. He kept the temperature at about 70°, and took care that the patient should have plenty of fresh air. Into the hot water in the atomizer he had a teaspoonful of "Listerine" poured, as a disinfectant; but he could not say positively whether this was really of service or not. In one case that he saw in consultation, the child was evidently suffering in consequence of the temperature of the room, which was so high that it was perspiring profusely, while its pulse was 180. In about two hours after the air had been rendered properly cool, however, the pulse came down to 110, and the child was much more comfortable in every way. This case also recovered under the use of bichloride of mercury.

DR. JOHN C. PETERS said that since the year 1845 he had seen every variety of treatment practised in so-called membranous croup, which was a disease for which so many remedies had been suggested that every one was entitled to his own views on the subject. In his own practice he had used antimony, iodide of potassium, iodine, and various other agents. For many years, however, he had treated almost all his cases of diphtheria with chlorate of potassium, crystals of the salt being placed dry upon the tongue. In his views of the pathology of this disease, as of many others besides diphtheria, he was a strict localist, believing that the trouble began in the throat and that from this absorption took place, and the general system became infected. Among the other drugs that he had used, also dry upon the tongue, were gallic acid, tannin, and alum. These astringents were not mixed with sugar or anything else, and he was sure that he had seen bad cases recover under their use in this way, as also under the effect of pepsin given in the same manner every half hour. The only adjunct that he employed was simple syringing with warm water to which salt, chlorate of potassium, or lime-water had been added. He had known one case to be treated successfully by a Cuban negress with a drug from Jamaica known as didividy, which seemed to be a bean in a pod something like the locust. It was used in infusion made with vinegar, and its medicinal properties were undoubtedly those of a simple astringent. Many years ago Trousseau and Bretonneau were appointed to investigate an outbreak of what was presumably diphtheria in a small district in France. The mortality was so great that sixty out of a population of six hundred perished; and they found, to their surprise, that the only one who had any success in the treatment of the disease was a female hog-doctor, who had a secret remedy for what she called "white sore throat" among pigs. This proved, on investigation, to be nothing more than a solution of alum in vinegar, and, on account of the good results obtained by it, alum came into general use. For his own part, Dr. Peters said, he had gradually arrived at the opinion that diphtheria was curable by more than one remedy. He had not as yet tried the bichloride of mercury, but he should be apt to use calomel dry upon the tongue.

DR. J. LEWIS SMITH remarked that the Seniors present would, no doubt, recall when calomel was in common use in the treatment of membranous croup. Before diphtheria appeared in this city in 1858, quite a notable case occurred at the Astor House. This was one of croup in which a number of eminent medical men pronounced that it was impossible that the child could live. As the case was so hopeless, a physician from the same place as the family of the latter, gave it, as a last resort, a dose of twenty grains of calomel dry upon the tongue, and from that time it began to improve. A prominent practitioner in New York still believed in the power of large doses of calomel, if given at the outset of the disease, to moderate its severity. He was sceptical himself about this, but he could not see that there would be any great objection to trying one large dose of calomel in the possible hope of its thus modifying the course of the attack; though he certainly should be unwilling to continue the use of the drug afterward. When diphtheria appeared here in 1858 the profession were disappointed in the effect of calomel, which was found only to add to the prostration incident to the disease, and the use of mercurials gradually became abandoned in New York, except by a very few.

Recently, however, there had been a revival of the mercurial treatment, and now the special preparation recommended was the bichloride. Dr. Smith then said that he had very carefully read the paper of Dr. Thallon, to which allusion had been made, and that he must say that he had failed to become convinced by the views expressed in it. The bichloride of mercury was recommended on account of its supposed germicide effect, and he was aware of the fact that it was the most powerful of the agents of this kind yet discovered; but he was very much in doubt whether it was entirely safe to believe that the bichloride actually had a germicide effect on the diphtheritic poison in the system. It was the theory that these antiseptic agents when introduced into the blood would destroy the disease-germs existing and developing there; but he was of the opinion that if they are brought into the blood in such strength as to accomplish this they would have a very destructive effect upon the economy, since these minute organisms were found to be as tenacious of life as the corpuscles of the blood themselves, and the normal cells would be destroyed at the same time.

All who were present at the last meeting, Dr. Smith continued, must have been delighted at the admirable

manner in which Dr. Wm. H. Welch described the anatomical characteristics of the exudations met with in membranous laryngitis. Whenever there was pseudo-membrane there was found the exudation from the blood (the fibrin), and, in addition, the altered epithelial cells, as held by Rindfleisch and all the other best authorities. Now fibrin was freely dissolved by alkalies, and in the experiments in which he had taken part at the New York Foundling Asylum, it was demonstrated that a two per cent. solution of liquor potassæ would dissolve it.

The next point to which he alluded was in regard to the epithelial cells, and here there was a difference of opinion as to whether alkalies would dissolve the epithelial element of the pseudo-membranes or not. By some writers this portion of the membrane was considered analogous to *mucine*, and mucine could readily be shown to be dissolved by a weak alkaline solution. On the whole, he believed that he must still adhere to his opinion that the inhalation of medicated steam formed a very important part of the treatment of this disease; and the solvent which he preferred, as he had mentioned at one of the recent meetings of the Section, was a two per cent. solution of liquor potassæ in lime-water containing an excess of lime, which rendered it more turbid than ordinary lime-water.

In regard to the cases reported by Dr. Thallon in his paper, they were not altogether convincing as to the preëminent efficiency of bichloride of mercury. Thus, in one of them, in addition to the internal medication, inhalation of chloride of ammonium was used, and as this agent was an alkali, it seemed probable that it had some effect in producing the favorable result noticed. Again, Dr. Thallon regarded as cases of croup those in which there was simple huskiness, without dyspnœa; but if he (Dr. Smith) were to do the same, he would be apt to report that fully one-half of his cases of croup recovered under the use of inhalations of a two per cent. solution of liquor potassæ with lime-water. If huskiness came on, he believed it was demanded, as a matter of safety, that such inhalations should be resorted to for the purpose of preventing further advance of the disease, for if there was only a slight deposit of membrane, it would probably be dissolved away at once. Muco-pus of a tough and viscid character, and situated lower down in the respiratory tract than the pseudo-membrane, formed, in connection with the membrane above, one of the causes of dyspnœa, and when the mucine present was dissolved by these alkaline inhalations, the pus was rendered thinner and more easily expectorated, which he thought was a very important point as regards the efficacy of the treatment. At the late meeting, of which he had spoken, he had stated that in his opinion nothing should be used as an application, by inhalation or otherwise, which was an irritant. Within the past month, however, he had seen the use of such a caustic as nitrate of silver advocated, and he believed that the Academy, as a scientific body, ought to protest against the employment of any such measure. This was the objection he had against the use of bromine, which had been so highly lauded, particularly by one authority in this city; it was too irritating.

Dr. Smith had been more and more impressed, as his experience extended, with the very great importance of alcohol in the treatment, and whether the disease was due to the presence of a micrococcus or not, its free administration was, as a rule, indicated. It was surprising what large quantities of alcohol were tolerated by the system under the circumstances, and it was no uncommon thing to see a child one year old, taking with advantage, a teaspoonful of brandy or whiskey every hour. He should be glad to make a trial of Dr. Pepper's treatment, as endorsed here to night; but so far as the efficiency of the method was demonstrated by the cases published by Dr. Thallon, he must confess that he was not convinced of its superiority, on account of the character of the cases reported.

Dr. Jacobi thought that it was hardly fair to class the calomel treatment with that of the bichloride of mercury, as Dr. Smith had done. It was not a matter of indifference whether we gave a dose of twenty grains of calomel at the beginning of an attack of croup or not. If he gave an adult twenty or thirty grains of this drug, even if it was taken dry on the tongue (in which case less griping would be produced), he always expected such well-marked effects as loose calomel passages. The bichloride was less liable to produce salivation than any other preparation of mercury. It had been stated that if antiseptic agents were given in sufficient strength to destroy bacteria, they would also destroy the cells of the blood. This was indeed true of carbolic acid and all the other ordinary germicides, but it was not true of bichloride of mercury. The body of a child, four or five years old, contained about two and a half pounds of blood; and it had been demonstrated beyond question that one grain of the bichloride was sufficient to destroy all ferment in such a quantity of blood, while it was, at the same time, incapable of destroying the blood-corpuscles.

It had, furthermore, he said, been shown that bichloride of mercury was probably the only germicide which could be introduced into the blood in an unchanged condition. Dr. Welch had stated, at the last meeting of the Academy, that there was as yet no proof that diphtheria was produced by any micrococcus. Since, therefore, the question was still undecided, he would not dwell upon it.

He looked upon the bichloride of mercury simply as an anti-fermentative agent. The practical results of its employment in croup had seemed to him eminently satisfactory, as compared with other agents; and whether a satisfactory explanation of its mode of action could be given at the present time or not, it did not matter; he was willing to wait for that. He would, before closing, again lay stress on the fact that when the bichloride was used, the dose, which should be sufficiently large, should be repeated very frequently, so as to get enough of it into the system as rapidly as possible. In one or two instances he had given as much as a grain in the twenty-four hours, and even a child of five months should receive, at least, half a grain in that period. The dose, however, should not be too large; and since he had known of the effect produced in the case which he had seen with Dr. Forest, he had been more cautious than before, and was also very particular to have the bichloride largely diluted. Given with proper care, there were no bad results whatever from its use.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, April 7, 1884.

William Hunt, M.D., in the Chair.

Dr. Wm. G. Porter related the following

CASE OF BIGELOW'S OPERATION AT TWO SITTINGS.

B. S., white, U. S., single, æt. 17, boilermaker, temperate, admitted to the Presbyterian Hospital on November 12, 1883, had suffered from symptoms of stone in the bladder for about four years previous to admission. General health good, passes urine three or four times a day, and once or twice during night. Urine showed abundance of pus with blood and one-fifth albumen. No trace of urates, phosphates, or tube-casts. On passing a sound, the presence of a stone was readily detected. The patient was exceedingly nervous and sensitive and a great coward, and consequently no attempt was made to ascertain the size of the stone until the patient was prepared for operation. On November 17, he was etherized, and the stone seized with a medium sized lithotrite, showing a long diameter of about two and a half inches and a short diameter of about one inch. The lithotrite was now tightened, and as the stone seemed to crush readily, the operation of Bigelow was decided on. After crushing easily for some time, and considerably diminishing the size of the stone, the ordinary sized lithotrite, which had been used, failed to make any further impression on the stone with any amount of force which it was considered safe to use. The Bigelow evacuator was now introduced, to permit of which the meatus had to be enlarged, and 370 grains of sand and small fragments were evacuated. Some cystitis followed the operation, and nothing more was done until December 3, sixteen days after the first operation, when, being provided with a Bigelow lithotrite, the remainder of the stone was easily broken and 270 grains evacuated, making 640 grains in all.

Considerable œdematous swelling followed the second operation, and in a few days an abscess formed at the junction of the penis with the scrotum, which was evacuated and discharged a large quantity of fetid pus. Urine was discharged through the resulting sinus for a week or ten days, but it gradually closed completely and the patient was discharged. On December 24, a thorough exploration of the bladder failed to detect any evidence of the presence of fragments.

Dr. S. W. Gross suggested that the title of this paper should be changed to "Lithotrity at Two Sittings." It was not a Bigelow operation, which consists in evacuating the bladder at one sitting, no matter whether it requires twenty minutes or three hours.

Dr. Porter said that Dr. Bigelow, in his original description, after stating that the stone should be comminuted, not necessarily pulverized, went on to say that this operation can generally, not always, be performed at one sitting. The other points to which he draws attention in this operation are the use of a larger tube than usual for evacuation, the immediate evacuation of all the fragments, the thorough washing out of the bladder, and the great length of time which may be safely occupied in the performance of this operation, it being continued under ether one or two hours, if necessary. If requisite, the urinary meatus may be enlarged to allow the passage of the large tube. Under these circumstances he thought that the title of the paper was correct, and that it was a Bigelow operation. It was done, it is true, at two sittings. It might as well have been done at one if he had had the proper lithotrite. The small ordinary lithotrite would not crush the stone; he removed the small fragments and washed out the bladder. When the patient had recovered from this operation he used the Bigelow lithotrite, and had no trouble in crushing and removing the fragments.

Dr. Wm. Hunt said that this was simply a question of fact, and he understood that Dr. Gross would insist upon the immediate evacuation of the bladder as an essential part of Bigelow's operation.

Dr. Porter claimed that Dr. Bigelow did not insist on it. In one of the cases which he described, the operation was completed in two sittings.

Dr. Willard narrated a case of small stone in a man of twenty-eight, who, when he first saw him, was able to get a No. 26 sound through the urethra, but this caused slight pain. He afterwards gradually dilated the urethra until he could pass a No. 31, but each passage of the sound was followed by fever. The introduction of a lithotrite to measure the stone caused a chill which was followed by fever, the temperature reaching 104° Although he was kept in bed, and quinine and morphia given after each sounding, the temperature has always gone up, sometimes not over 100°. He desired to know whether it would be better to dilate the urethra and crush the stone, or to perform lithotomy.

Dr. Brinton said he would advise lithotomy.

Dr. S. W. Gross concurred.

Dr. J. Ewing Mears exhibited a specimen of

CARCINOMA OF THE BLADDER,

which was removed from a man admitted to St. Mary's Hospital March 25, 1884. The man, when admitted, was almost unconscious, and only a very imperfect history could be obtained. He was eighty-two years of age. There was dribbling of urine, a great deal of sensitiveness over the region of the bladder and lower part of the abdomen on palpation and percussion. A catheter was introduced and a large quantity of urine containing a small quantity of blood, pus, and epithelial cells was passed. The case was treated by hot applications over the lower part of the abdomen, the use of a catheter, and a general supporting treatment. The patient gradually sank, and died four days after admission.

At the autopsy, which was made by Dr. R. B. Wetherill, Resident Physician, a fungoid growth was found to spring from the bas fond of the bladder extending to and involving the prostate gland. The growth was symmetrical, occupying the median line of the organ, and about three and a half inches in diameter. It projected about half an inch above the inner surface of the bladder, and was soft to the touch. Before incision of the tumor, the cut surfaces were white and glistening, exuding a white, milky fluid. The deeper portions were more dense. Small, dense, white, circumscribed growths, about the size of a large pea, were found in various parts of the bladder. The bladder was hypertrophied and thickened throughout. At the upper portion there were appearances of incipient gangrene.

Sections were made of the growths, which exhibited under the microscope a fibrous stroma, alveoli filled with epithelial cells; no stroma between the cells.

According to the statement of the patient, the growth was very rapid. The first trouble noticed was twenty-one weeks before admission. The only symptom calling attention to any other condition than that of chronic cystitis was the passage of a small quantity of blood. That did not, however, attract very much attention, as the amount was small. Carcinoma of the bladder of this variety was, he thought, rarely met with.

DR. NANCREDE reported the following case of

TREPHINING FOR BRAIN ABSCESS.

A boy had a punctured fracture of the skull, made with a knife. The blade was removed rather rapidly. The boy had convulsions afterwards. He took out a disk of bone and passed a probe into the substance of the brain, looking for pus or serum, which he expected to find, but could detect nothing. Erysipelas set in, but did not affect the wound. He next had a subnormal temperature, a little nausea, headache, and an occasionally slow pulse.

On the 22d he was reported dying. The right side was paralyzed, the lower extremity more than the upper. When Dr. Nancrede took hold of the flap, he made a slight motion of the left side. He found the dura mater on a level with the opening, and pulsating freely. He incised the dura mater, but not a particle of pus escaped. He passed the aspirator-needle in four directions into the brain substance for a distance of two-thirds of an inch, but no pus was found. He applied a large trephine below in front of the wound. When he had gotten into the diplöe, the respirations had stopped, then the pulse at the wrist stopped, and the assistants thought that the heart had stopped. He completed the trephining as rapidly as possible. He opened the dura mater, but not a particle of pus was found. Fortunately, in making pressure, a little pus was seen to ooze through one of the needle punctures, and making an opening into the brain substance at this point, over an ounce of pus escaped. Artificial respiration was then resorted to, but it required considerable time to bring him into a condition where he could be left. He then breathed naturally, regained consciousness, and the paralysis diminished. He lived six and a half days after this, and finally died of sheer exhaustion from a second attack of erysipelas.

Dr. Nancrede said he had not been able to go over the subject very thoroughly, but he was not aware of another instance in which trephining was resorted to after the patient had ceased to respire. The patient was not under the influence of ether.

NEW INVENTIONS.

A CHEAP AND PRACTICAL METHOD OF ELECTRIC ILLUMINATION FOR LARYNGOSCOPY, ETC.

BY SOLOMON SOLIS-COHEN, A.M., M.D.,
FELLOW OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION, ETC.

AFTER considerable experimentation, and trial of several of the more or less elaborate forms of "electric laryngoscopes" devised by Helot, Trouvé, and others, I have found a return to "first principles" to furnish at once the cheapest, most convenient, and most satisfactory method of electric illumination that has thus far come to my notice.

We need simply substitute a small incandescent lamp for the gas or coal-oil flame in the Tobold or other illuminating apparatus. These lamps can be purchased for $1.50 at any of the electric-supply shops, and can easily be mounted in place, with a current-switch attachment, by any competent workman.

The battery I have used is Flemming's "Universal Battery"—the same employed for galvano-cautery—the constant current from ten cells being sufficient to produce a soft, white light of greater intensity than the coal-oil or gas flame, and inferior only to sunlight.

For ordinary office use, I prefer the Tobold lantern, with adjustable reflector.

For direct illumination, a bull's-eye lens is required, such as is used by Helot and Trouvé; and this can also be utilized for reflection at a distance by those who prefer a reflector worn on the head to that of the Tobold system.

For office use, however, in connection with a head-band reflector, the incandescent lamp with the bull's-eye lantern known as the "Mackenzie Condenser," is superior in illuminating power to Trouvé's instrument ("Photophore"). Mounted on the Mackenzie bracket, with either the Tobold or Mackenzie lantern, this illuminator leaves little to be desired; for should the loop of the lamp burn off, or the battery give out,[1] we can turn on the gas.

CORRESPONDENCE.

THE DANGER OF GLASS VAGINAL SPECULA.

To the Editor of THE MEDICAL NEWS.

SIR: I was summoned yesterday to see—at once—a young married lady, who was suffering, I was told, from leucorrhœa (a flow of whites from the vagina), which does exist as such, but is denied by my friend, Dr. Addis Emmet, who does not describe it in his admirable book because the flow of whites, he says, always comes from the endometrium, and is the consequence of catarrhal inflammation of the mucous membrane of the uterine or cervical cavity and canal. I would refer Dr. Emmet and those gentlemen denying the existence of leucorrhœa in women to the description of the vaginal and vulval mucosa in Charles Heitzmann's *Microscopical Morphology of the Animal Body in Health and Disease*, p. 838, where this author says: "The *mucosa* of the vagina is raised in folds (rugæ), and in this situation papillæ are present. . . . The papillæ are simple throughout the *mucosa*, but compound at the height of the rugæ and toward the vestibulum. . . . In the *mucosa* varying numbers of lymph-corpuscles are found, arranged, sometimes, in circumscribed follicular formations. The covering epithelium is stratified, blending with that of the cervical portion of the uterus. . . .

[1] The same remark applies when the galvano-cautery battery is used for the illuminator, and we desire to change the current and employ it for another purpose. Since the above was in type, I have found that it is only with fresh battery fluid that we can get the best results. With old fluid, the light is no better than gas, if not inferior to it.

Blood- and lymph-vessels produce plexuses above the epithelial cover and below the muscle-layers, which hold a large number of veins. In the vestibulum, the *mucosa* contains small, acinous, mucous glands, which are more numerous around the opening of the urethra and on the clitoris. The Bartholinian glands are also large mucous glands. The hymen is a reduplication of the vaginal mucosa, very rich in bloodvessels and nerves. The labia majora are rich in smooth muscles and fat. The clitoris is covered by a *mucosa*. . . . The labia minora are characterized by the presence of numerous sebaceous glands."

It must be evident from the description quoted that in inflammation of the vulva or the vagina, or of both, we have an increased flow of whites, which in Greek is termed *Leucorrhœa*. Why should so-called catarrhal inflammation not occur here as well as in other organs of the body where there is an epithelium or a *mucosa?* Without saying any more regarding the existence of the symptom, leucorrhœa—a symptom like that of diarrhœa occurring in inflammation of the intestinal tract—I wish to call attention to the danger of using glass tubes by women suffering from leucorrhœa, like the patient whom, as I stated above, I was called upon to see, on account of a piece of broken glass lodging in her vagina, which caused bleeding and immense mental anxiety.

The lady was advised by her physician to use salt-water injections into her vagina, to cure her leucorrhœa, and, while inserting the glass tube into her vagina, it broke, and caused the bleeding and the great distress, to relieve which I was summoned in great haste. I found the patient—aged about twenty-three—ghastly pale, with both thighs widely separated, holding on cautiously with her hands to the bedpost. She dared not move, fearing that the glass piece in her vagina might cut her womb off, as she said, especially as she noticed, to her sorrow, blood streaming down her legs. She had ceased to menstruate a week before the accident. I introduced the index finger of my right hand cautiously into her vagina, and, reaching up to the fornix, behind the uterus, I discovered the *corpus delicti*, which I removed, guarded by my fingers. I syringed the vagina of all blood-clots, stopped the hemorrhage, and left the lady—an actress—very comfortable; and I learned next morning that she played her part that evening at the New York Casino, where she is professionally engaged.

I report this case—probably not a rare one—for the purpose of advising physicians to discountenance the use of glass tubes for vaginal douching, and to recommend hard-rubber tubes instead.

I am, yours, very respectfully and truly,

Rudolf Tauszky, M.D.

171 E. Seventieth Street, New York.
July 10, 1884.

NEWS ITEMS.

Cholera Precautions. Instructions to United States Consular Officers.—Secretary Frelinghuysen on Monday instructed, by cable, the consular officers at London, Liverpool, Marseilles, Havre, Bordeaux, Bremen, and Hamburg at once to appoint competent physicians to inspect all vessels and passengers departing for the United States from those ports. The consular officers are instructed to refuse clean bills of health in all cases except upon the recommendation of the sanitary inspector that such bills be given. The consuls are instructed to report by cable any case of infectious or contagious disease known to exist on board of a vessel at the time of her departure for the United States. This course is adopted in order that the health officers in United States ports may have timely warning of approaching danger, and be prepared to take such measures as shall prevent the scourge from gaining a foothold in this country.

The American Consul at London announces that vessels from Europe must have certified clean bills of health from the American consul at the port from which they sail, or they will not be allowed to enter American ports.

It is probable that under the authority conferred by the contagious disease clause of the Legislative, Executive, and Judicial Appropriation Bill, medical examiners will be appointed as attachés to the American consulates at the French ports infected with cholera, whose duty it will be to report periodically upon the progress of that disease.

Precautions in Illinois.—The Illinois State Board of Health, with commendable promptness and celerity, has sent the following circular to the Mayors and Presidents of Village Boards of eight hundred and forty-four cities, villages, and towns of the State:

"At the recent meeting of the State Board of Health, held in Springfield, July 2 and 3, 1884, the following resolution was adopted:

"*Resolved*, That, while epidemic cholera may be excluded from this country by thoroughly enforced quarantine regulations, yet the best attainable sanitary condition of every locality in the State should be secured, so that in the event of Asiatic cholera effecting an entrance, notwithstanding quarantine, the disease may be met and fought under the most favorable circumstances; and the Secretary is, therefore, hereby authorized to take such action as in his judgment will most promptly obtain a thorough sanitary organization of the State, and the adoption and enforcement of the measures necessary to improve its general sanitary condition.

"It is entirely possible that we may escape a visitation of Asiatic cholera this year, although there is yet plenty of time for the disease to reach our shores before cold weather. But even if there were no danger from this source, it should be remembered that everything which is done in the direction of sanitary improvement benefits the general health, reduces the amount of sickness, and lessens the death-rate. An obvious duty, therefore, rests at all times, but more urgently at present, upon those charged with the administration of public-health affairs to take such steps as may be necessary to remedy any defects in the existing sanitary status.

"To this end a general inspection of the entire territory under your jurisdiction should be made forthwith; and all nuisances, or other conditions injurious to the public health, which may be disclosed by such inspection, should be promptly abated. Especial attention should be paid to—

"*First.* The condition of the water-supply.

"*Second.* The disposition of night-soil, garbage, and sewage.

"*Third.* The cleansing of streets, alleys, and other public places.

"*Fourth.* The supervision of food-supplies, and of market-places, slaughter-houses, and similar establishments.

"*Fifth.* The general sanitation of every house and its surroundings.

"1. Water is one of the commonest mediums through which cholera spreads; but, aside from this, typhoid and malarial fevers, diarrhœa, dysentery, and other diseases, are caused by impure and polluted water. Hence the necessity of protecting the supply from contamination by surface-washings and drainage of filthy soil or premises, or of wastes from manufacturing establishments, or by leakage through the ground from privy-vaults, cesspools, etc.

"2. Night-soil, garbage, sewage, and all other forms of decomposing organic matter, are highly prejudicial to health, and their foul odors are indications of danger. The various methods for their proper disposal, so as to render them harmless, are well understood, and should be enforced according to the varying conditions of each locality.

"3. Clean streets and alleys, and gutters properly drained and kept free from unsightly and filthy accumulations, are of even greater importance during the heat of summer than at other times. The healthy condition of the atmosphere of a locality largely depends upon the condition of its thoroughfares.

"4. The rapid decomposition of most articles of food during hot weather—the tainting, souring, wilting, or rotting processes—and the derangements of the stomach and bowels caused by the use of such food, indicate the necessity for special supervision at this time of all food-supplies, and of the places where they are prepared, stored, or disposed of.

"5. The foundation of healthy living is, obviously, the individual home and its surroundings. Houses, cellars, yards, and outbuildings should be carefully inspected, and all accumulations of garbage, refuse, and filth of every description should be removed, or, where this is not practicable, they should be rendered harmless by appropriate treatment. No house or premises can be healthy without proper drainage. If this is not secured by sewers or underground drains, then recourse should be had to surface drains, so as to prevent the possibility of stagnant water under the dwelling or in its vicinity. Cellars should be dry, clean, and well ventilated, so that they may not generate foul air to be drawn up through the house.

"It is desired that this work of inspection, and remedying of evils and defects, be begun at the earliest practicable moment, and a preliminary report be made to this office, covering, in a general way, the existing sanitary condition, and the measures adopted and enforced for its improvement."

QUARANTINE IN LOUISIANA.—The Louisiana State Board of Health has adopted the following:

Whereas, Cholera is known to exist in Toulon and Marseilles in epidemic form, be it

Resolved, That the President of the Board instruct the quarantine officers at all the quarantine stations in the State to detain all vessels coming from those ports, or any other ports where cholera may exist, until further orders from the Board.

FOREIGN PRECAUTIONS.—The Cuban authorities have ordered that all vessels arriving from French Mediterranean ports, or from any port at which cholera prevails, shall be detained seven days for observation if they bring a clean bill of health, or ten days if they bring an unclean bill. If they had or have cholera on board they will be subjected to a rigorous quarantine at the station of Mariel or Santiago de Cuba. The order also applies to all vessels from Asia or Africa.

The Spanish Government has ordered a quarantine against vessels arriving from German ports because the precautions taken by Germany against the spread of the cholera are not deemed sufficient.

Italy is now inaccessible except *via* Austria. English passengers by the Indian mail can no longer get through by way of St. Gothard, as hitherto. Quarantine was established July 11th, at Chiese. The only way of getting to Italy now is *via* Vienna.

The Austrian Government has asked the Porte to cooperate with it in the adoption of measures to prevent the introduction of cholera into Turkey and Austria.

A quarantine of two weeks has been established at Odessa against vessels arriving from French Mediterranean ports, or other ports at which cholera is known to prevail.

During the cholera epidemic vessels from infected ports are forbidden to land passengers or cargo at any port in Portugal.

The Colombian authorities have ordered the enforcement of quarantine regulations in respect to vessels arriving at Panama from Europe.

DR. KOCH ON THE CHOLERA EPIDEMIC.—The *N. Y. Herald* of last Saturday contains a special cablegram, giving the report of an interview, at Toulon, with Dr. Koch, published in the *Gaulois* of the preceding day. Dr. Koch is represented to have said that "all the post-mortems made confirm the results of my first investigation, which put the Asiatic character of the scourge beyond question. I have found the same phenomena, as in the cases which I investigated in India. The microbes were identical. I found numbers in the body of that soldier, Besnard, whose post-mortem I made on Sunday evening. Indeed, I found more than I had seen in Egypt. Messrs. Strauss and Roux, who were standing by, also recognized the presence of the Indian microbe in Egypt, but had always seen it mixed with others: whereas in post-mortems that I have made here the Indian microbes outnumbered the others immensely."

"The microbe is rarely met with in the stomach. Gastric disorders are not favorable to it, so it takes refuge in the small intestines, where it can easily multiply. The microbe in the intestines causes diarrhœa and vomiting, leading to thickening and chilling of the blood, then it secretes an intoxicating poison, which causes the dry, instantaneous cholera—*foudroyant sec*—that is, cholera without diarrhœa.

"Contamination is not caused by air, but by absorption of microbes infecting food, especially water and solid food introduced into the digestive tubes. Hence

I advised the members of the Sanitary Committee to shut up the wells and counsel the people to drink boiled water, or water from non-infected places, or light mineral waters. It also explains the necessity of taking only well-cooked food, peeled fruits, vegetables and preserves. Remember, microbes die if exposed to a high and especially to a dry temperature.

"I hold that microbes are transmissible only by excrement or objects soiled by excrement. Consequently the first precaution to take is to subject the linen of cholera patients to heat, hot air, and phenic acid more or less concentrated. Microbes cannot live in concentrated solutions of phenic acid or in a dry atmosphere. They develop and multiply in the damp. They have been found in ponds in cholera countries. No soiled object is the least dangerous when once it is dry, for the microbe has become powerless to reproduce itself; indeed, it is dead.

"The theory of the destruction of the microbe by dryness leads me to advise the closing up and drying of contaminated apartments for several days, and to pronounce the disinfecting of luggage, letters, and travellers ineffectual.

"The practice of watering streets and boulevards is dangerous. It favors the conditions needed for the reproduction and propagation of microbes. It would be preferable to leave the streets dry and dusty.

"I think I may say that, considering the precautions taken by the naval authorities, cholera was imported on some merchant ship, probably English. They do not scruple on English vessels to hide deaths which occur on voyages or to falsify logs.

"I disapprove of crowds altogether. All public fêtes and fairs should be forbidden."

YELLOW FEVER has appeared in Guaymas, Mexico, to such an extent as to be no longer denied, and several cases are reported at Mazatlan, and the inhabitants are fleeing to the mountains.

Deaths from this disease in Havana during the month of June numbered sixty-eight, thirty in the Military Hospital, and the remainder among the civilians.

THE PLAGUE has made its appearance at Pskov, Russia, and is represented to be entirely beyond control,

---

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 8 TO JULY 14, 1884.

CLEMENTS, B. A., *Major and Surgeon.*—Also directed to relieve Surgeon J. P. Wright of his duties as Acting Medical Director, Department of the Missouri.—*Par. 1, S. O. 138, Headquarters Department of the Missouri,* July 8, 1884.

PROMOTIONS.

To be Assistant Surgeons with the rank of Captain, after five years' service, in accordance with the Act of Congress of June 23, 1874:

Assistant Surgeon JOHN J. KANE, June 3, 1884.
Assistant Surgeon JOHN M. BANISTER, June 3, 1884.
Assistant Surgeon AARON H. APPEL, June 3, 1884.
Assistant Surgeon CHARLES RICHARD, June 3, 1884.
Assistant Surgeon W. FITZHUGH CARTER, June 3, 1884.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM APRIL 1 TO JUNE 30, 1884.

BAILHACHE, P. H., *Surgeon.*—Detailed as Chairman of Board to examine candidates for appointment into the Revenue Marine Service, May 17, 1884.

VANSANT, JOHN, *Surgeon.*—To proceed to Empire City, Oregon, as inspector, April 2, 1884.

HUTTON, W. H. H., *Surgeon.*—Granted leave of absence for twenty-five days, May 14, and June 9, 1884.

MILLER, T. W., *Surgeon.*—Granted leave of absence to attend the meeting of the American Medical Association, May 1, 1884. To proceed to Pittsburg, Pa., Ashtabula, Ohio, Buffalo, N. Y., and Detroit, Mich., as inspector, May 10, 1884.

WYMAN, WALTER, *Surgeon.*—To proceed to Crisfield, Md., as Inspector, April 11, 1884. Detailed to represent the Marine-Hospital Service as delegate to the American Medical Association, April 17, 1884. Detailed as President of Board for physical examination of candidates for appointment as cadets in the Revenue Marine Service, May 20, 1884. To examine cadet-graduates, Revenue Marine Service, as to physical qualifications, May 31, 1884. Detailed as member of Commission to inspect United States buildings at quarantine station on the Delaware River, June 16, 1884.

AUSTIN, H. W., *Surgeon.*—Granted leave of absence to attend the meeting of the American Medical Association, May 2, 1884.

GASSAWAY, J. M., *Surgeon.*—When relieved by P. A. Surgeon Mead, to proceed to Portland, Maine, and assume charge of the Service, April 26, 1884. Granted leave of absence for thirty days, May 28, 1884.

STONER, G. W., *Passed Assistant Surgeon.*—When relieved by Surgeon Gassaway, to proceed to Cairo, Illinois, and assume charge of the Service, April 16, 1884. When relieved by Surgeon Gassaway to report in person to the Surgeon-General, June 20, 1884.

IRWIN, FAIRFAX, *Passed Assistant Surgeon.*—Granted leave of absence for twenty-one days, June 19, 1884.

MEAD, F. W., *Passed Assistant Surgeon.*—When relieved by Assistant Surgeon Devan, to proceed to Philadelphia, Pa., and assume charge of the Service, April 16, 1884. Detailed as Recorder of Board for physical examination of candidates for appointment as cadets in the Revenue Marine Service, May 20, 1884.

CARTER, H. R., *Passed Assistant Surgeon.*—To inspect unserviceable property at the San Francisco Hospital, May 24, 1884.

WHEELER, W. A., *Passed Assistant Surgeon.*—To inspect unserviceable property at the Chicago Hospital, May 24, 1884.

BENSON, J. A., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, April 14, 1884. When relieved by P. A. Surgeon Stoner, to report to him for temporary duty, May 19, 1884.

BANKS, C. E., *Passed Assistant Surgeon.*—Detailed as member of Board to examine physically candidates for appointment into the Revenue Marine Service, May 17, 1884. To inspect unserviceable property at Baltimore, Md., New York, N. Y., and Boston, Mass., May 26 and June 2, 1884.

BENNETT, P. H., *Assistant Surgeon.*—Granted leave of absence for twenty days, June 28, 1884.

DEVAN, S. C., *Assistant Surgeon.*—To proceed to Port Townsend, W. T., relieve P. A. Surgeon Mead, and assume charge of the Service, April 14, 1884.

URQUHART, F. M., *Assistant Surgeon.*—Granted leave of absence for thirty days, May 22, 1884.

YEMANS, H. W., *Assistant Surgeon.*—To report to Captain M. A. Healey for duty as medical officer during cruise of Revenue Cutter "Corwin," April 16, 1884.

GLENNAN, A. H., *Assistant Surgeon.*—To proceed to Mobile, Ala., for temporary duty during sickness of P. A. Surgeon Goldsborough, June 17, 1884.

APPOINTMENT.

BROOKS, STEPHEN D., M.D., of Massachusetts, having passed the examination required by the Regulations, was appointed an Assistant Surgeon by the Secretary of the Treasury, May 15, 1884. (Dr. Brooks had previously served as an Acting Assistant Surgeon from March, 1883 to May, 1884.)

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLV. SATURDAY, JULY 26, 1884. NO. 4.

ORIGINAL LECTURES.

A COURSE OF LECTURES ON DERMATOLOGY.

Delivered at the University of Pennsylvania during the Session of 1883–1884.

BY LOUIS A. DUHRING, M.D.,

PROFESSOR OF DERMATOLOGY IN THE UNIVERSITY.

(Reported by Henry Wile, M.D.)

LECTURE V.

LENTIGO; CHLOASMA; NÆVUS PIGMENTOSUS; MOLLUSCUM EPITHELIALE; CALLOSITAS; CLAVUS; CORNU CUTANEUM; VERRUCA; ICHTHYOSIS; HYPERTROPHY OF THE HAIR; SCLERODERMA; MORPHŒA; SCLEREMA NEONATORUM; ELEPHANTIASIS ARABUM; DERMATOLYSIS.

HYPERTROPHY OF THE SKIN consists of an increase in its elements, and there may be hypertrophy of pigment, as in chloasma; hypertrophy of epidermis, as in ichthyosis; hypertrophy of connective tissue, as in elephantiasis. It is characterized, as a rule, by the absence of inflammation, and rarely occasions serious inconvenience. The course is, as a rule, slow, the affection generally lasting a lifetime.

LENTIGO, or freckle, is a common form of pigment deposit, characterized by irregularly shaped, pin-head or pea-sized, yellowish or brownish spots, found usually on the face and backs of the hands. They are often induced by the rays of the sun, and may be present in such numbers as to disfigure the individual. Besides the face and hands, they may occur on other parts of the body, and are liable to persist for an indefinite time. They occur, for the most part, on blondes. Occasional black freckles are also now and then met with. As regards treatment, the most satisfactory consists of local measures, and among the remedies corrosive sublimate is the best, used in the form of a lotion, one to three grains to the ounce of water or emulsion of almonds. The application should be made morning and evening, and kept up until a certain amount of desquamation takes place.

CHLOASMA is characterized by variously sized and shaped, smooth, yellowish or brownish discolorations, occurring usually about the face. The affection is divided into varieties according to the cause, as idiopathic or symptomatic. Under the first are included those forms produced by the rays of the sun, sinapisms, long-continued scratching, as in pediculosis, etc. Under the second belong those forms occurring in the course of certain internal diseases, as chloasma uterinum, which may occur in the married or single, and is influenced by certain conditions of the uterus. It appears, as a rule, upon the forehead or cheeks in the form of dirty-looking, yellowish or brownish patches, which are often extremely disfiguring. It is rarely so marked in single women as in those that are married and have been pregnant. The same form of chloasma is sometimes observed in men. The causes are numerous, and traceable in many instances to the nervous system. This observation is being more and more corroborated every year. The disease is not uncommon among the insane and those who have suffered from nervous shock. In some cases, instead of being localized, the discoloration is diffused uniformly or in patches over the whole integument. The pathology of the affection consists of an abnormal deposit of pigment in the mucous layer of the epidermis. As to the diagnosis, it may be confounded with tinea versicolor; but the former is smooth, and presents no scaling, while the latter is scaly, and usually extends itself over large areas.

Under chloasma is also classified the pigmentation of the skin occurring in *Addison's disease;* also the condition following the continued exhibition of nitrate of silver, known as *argyria*. Somewhat analogous to the foregoing is that resulting from the practice of *tattooing*, in which certain pigments, as vermilion and charcoal, are introduced into the skin. The most valuable remedy in the treatment of the various forms of pigmentation is corrosive sublimate, one to five grains to the ounce of alcohol or water, dabbed on the part two or three times a day, until a certain amount of desquamation is produced. After the pigment is thus removed it is liable to return, but it does not always do so. Vleminckx's solution, diluted one part to three or six, also sometimes acts happily.

NÆVUS PIGMENTOSUS consists of a circumscribed deposit of pigment of varying size and shape. It may be single or multiple, congenital or acquired. It is oval or irregular in shape, and may occur on any part of the body. When smooth and soft, it constitutes the *nævus spilus;* when rough and warty, *nævus verrucosus;* when accompanied by thickness and growth of fatty tissue, *nævus lipomatodes;* when covered with growth of hair, *nævus pilosus*. The treatment consists in extirpation or the application of caustics; the former is preferable. Caustic potash or nitric acid is here to be used with caution.

MOLLUSCUM EPITHELIALE has been carefully studied as to its pathology, and found to be an epithelial formation. Various names have been proposed, but the best is that given by Virchow many years ago, and adopted here. It is a rare affection in this country, but commoner in Great Britain. It is characterized by rounded, semi-globular, pin-head to pea-sized, whitish or pinkish papules or tubercles. They have a distended, often waxy look; are slightly flattened, and at the summit is a dark point constituting the opening of the follicle. The affection occurs, for the most part, among poorly, ill-nourished children, more rarely in adults. Some authorities contend that it is contagious, but Dr. Duhring has never seen any positive evidence offered in favor of such a view. It may, however, come in form of epidemics. Regarding its pathology, authorities are divided

into two factions: one regarding the disease as originating in the sebaceous gland; the other viewing it as a disease of the rete. Dr. Duhring believes in both theories, namely, that it is a disease of the rete, taking its origin, however, in the hair-follicles, becoming a hyperplasia of the epithelial lining and also of the sebaceous gland. Microscopically, it is found to consist of epithelial cells, with nuclei, and peculiar round or oval bodies called "molluscous bodies," and believed to be altered, fatty, degenerated epithelial cells. The disease may last two or three months, the lesions drying up or coming away as a slough. It is to be distinguished from molluscum fibrosum. The treatment consists of excision with the knife and subsequent application of a caustic, as nitrate of silver. Frequently, if left to themselves, they disappear spontaneously. Appearing on the face, however, they call for surgical interference.

Callositas is due to a hyperplasia of the epidermis, affecting the hands or feet. It is caused upon the hands by the continuous use of tools; it occurs, however, sometimes without such evident cause.

Clavus, or corn, is a circumscribed hyperplasia of the epidermis caused by continued pressure. There are two kinds, hard and soft, occurring, as a rule, upon the sides of the feet, especially on the toes. On section, it is seen to consist of an inverted cone, the point growing into and pressing down upon the corium, thereby often giving rise to pain. The treatment may consist in soaking the foot in hot water, or poulticing the corn for three or four nights, until the epidermis becomes softened and can easily be scraped away with the curette. Then, one drop of a solution of caustic potash, twenty to forty grains to the ounce, is cautiously applied, and the corn is destroyed. Salicylic acid, one scruple to two drachms of alcohol or water, is also a valuable application; it forms the basis of many corn cures. Another mode of treatment is that with plasters of sapo viridis, applied every night, say for a week, when often the greater part of the corn can be scraped out.

Cornu cutaneum is occasionally met with, and differs in nowise from the horn of lower animals. Cutaneous horns may be single or multiple, are found usually in elderly individuals, and sometimes attain the length of several inches. They occur, as a rule, on the backs of the hands, occasionally on the face, scalp, and sulcus of the penis. It is a pure epithelial formation springing from the rete. The treatment consists of removal and destruction of the base with some cauterizing agent, as chloride of zinc or caustic potash.

Verruca, or wart, either hard or soft, consists of variously sized and shaped papillary formations. *Verruca vulgaris*, or common wart, occurs about the hands, especially on the fingers. *Verruca plana*, or flat wart, is found on the back and about the shoulders. *Verruca filiformis*, consisting of a thin, thread-like formation, is encountered on the eyelids and neck. *Verruca digitata*, a broad excrescence with finger-like processes springing from the borders, is found upon the scalp. *Verruca acuminata*, also called cauliflower excrescence and venereal wart, is a pinkish, violaceous, or bright-red fleshy vegetation occurring usually about the genitalia of either sex, and often accompanies venereal disease, being caused by purulent secretion or excessive heat and moisture. It may also occur independent of any venereal disease. It takes on various forms, and, as a rule, appears like the head of a cauliflower or a cock's comb. It consists of a proliferation of the epidermis, the development being rapid; the papillæ of the corium and the corium itself are also greatly hypertrophied, and the bloodvessels dilated, rendering the growth exceedingly vascular.

The most satisfactory treatment of these growths is that by excision with the knife or scissors, and the cauterization of their bases by means of the nitrate of silver stick. They may also be removed with the galvano-caustic ligature, or treated with chromic or nitric acid or acid nitrate of mercury. In the treatment of venereal warts, astringent lotions and Labarraque's solution, together with some dusting powder, as of calomel, are highly useful.

Ichthyosis, or fish-skin disease, is met with not infrequently, and is characterized by a dryness, harshness or scaliness of the skin, and sometimes papillary growth. There are two varieties, *ichthyosis simplex* and *ichthyosis hystrix*. The former consists of a dryness or harshness accompanied by a variable amount of exfoliation, usually most pronounced upon the extensor surfaces, particularly about the knee and elbow joints. The latter is characterized by more or less pigmented, greatly hypertrophied papillæ. It is a congenital disease, and generally appears shortly after birth, first showing itself as a roughness of the skin, increasing from year to year, finally becoming scaly. Pathologically, it is a hypertrophy of the epidermis, and is one of the few incurable diseases of the skin. Much, however, can be done to alleviate the symptoms. The treatment consists of alkaline baths and soaps, and the use of glycerine and simple ointments.

Hypertrophy of the hair, as a general term, includes all variations as to size, number, thickness and length. The hair of the scalp may grow to an unusual length, and Dr. Duhring has seen a case in which it swept the floor. That of the beard may also attain great length, and there are cases on record in which it had reached the length of six feet. Hair may also grow upon regions where it is abnormal, as upon the face of a woman, whence the name "bearded women," who may at times be seen on exhibition. Then there are the "homines pilosi," or hairy people, on whom the excessive development of hair is both congenital and hereditary. There are also hairy races, as, for example, the Ainos, inhabiting an island north of Japan. Hairs are often seen upon verrucous formations, giving rise to *nævus pilosus*, being generally long and stiff. They are sometimes abnormal as to direction of growth, especially on the eyelids, giving rise to *trichiasis*. Another condition is known as *plica polonica*, where through neglect and filth the hair becomes entangled and matted together to such an extent that it cannot be combed. It was formerly common in Poland, but is rare in this country. *Hirsuties gestationis* consists of an abnormal growth of hair during pregnancy, after delivery the hairs usually falling out.

The treatment of superfluous hair is usually confined to moles and where the growth is upon the face of women. The only successful treatment is that by electrolysis, which consists of the introduction of a fine needle into the hair-follicle, the needle being connected with the negative pole of a galvanic current of from eight to sixteen cells, while the positive pole is held in the hand

of the patient. When the needle is introduced and the current is allowed to pass, a certain amount of frothing is produced, the papilla of the hair is destroyed, and the hair can easily be extracted. If the operation is properly and skilfully performed, the hair will not return. Success depends upon the practice, and the percentage of destroyed hairs is largely in proportion to the skill of the operator.

Scleroderma is an acute or chronic disease, characterized by a diffuse, more or less pigmented, rigid, stiffened or hardened, hide-bound condition of the skin. When typical, the skin is stiff, tight or immovable, and firm or hard to the touch. It may have a leathery feel, or may be hard like wood. There is, as a rule, yellowish or brownish pigmentation, occurring in irregular patches, producing a mottled condition, sometimes, also, neuralgia, pain or tingling, and generally a feeling of contraction. When attacking the face, the latter becomes expressionless, the features becoming immobile, and in an elderly person the wrinkles disappear, giving the individual a younger look. It usually attacks large surfaces, and may be attended with danger to life by preventing deglutition or respiration. It is usually general and symmetrical. The invasion is sudden or gradual, usually the latter, and it may run an acute or chronic course. The general health continues good, and the course of the disease is variable, lasting months or years, sometimes undergoing spontaneous involution. The causes are obscure. It is a very rare disease, occurring generally in early life or middle age, and is more common in women than in men.

The microscopic examination of the tissue throws little light upon the true nature of the disease, exhibiting a condensation of the connective tissue of the corium, with a deposit of pigment in the rete. It is generally regarded as a tropho-neurosis, being originally a hypertrophy leading later to atrophy. It is closely allied to morphœa, sometimes being associated with this disease. The former, however, as a rule, attacks large areas and is diffuse, while the latter appears in small patches and is circumscribed. The treatment consists in the internal administration of arsenic and quinine, and the use of stimulating ointments, baths, especially inunctions of oil, and the constant electric current.

Morphœa, also formerly called keloid of Addison, occurs in the form of patches, rounded, ovoid, or irregular in outline; small or large, soft or firm, tough or leathery, smooth or shining. In color they are pale yellowish or brownish, and often have a distinctly lardaceous look, like a piece of raw bacon set in the skin. In the early stage minute plexuses of bloodvessels may be seen around the patches, also more or less pigmentation in the form of a distinct halo. The lesions are, as a rule, asymmetrical, may attack any part of the body, more particularly certain regions, as the face, neck, chest, back and thighs. Becoming fully developed, they may remain stationary for months or years, or they may rapidly disappear, leaving the skin normal or atrophic. The course is generally chronic. The disease may also manifest itself in the form of atrophic, pit-like depressions in the skin, lines, streaks, or telangiectases. The causes are unknown. It occurs more often in women than in men, and is thought to be largely due to the influence of the nervous system. The pathological changes consist of a condensation of the connective tissue of the corium and a shrinkage of the papillary layer. The treatment should be stimulating and tonic. Arsenic is the best remedy, and is of value. It should be continued for six months or a year. The galvanic current should also be tried.

Hemiatrophia facialis, or unilateral atrophy of the face, is a form of morphœa, and consists of a variable degree of atrophy affecting part or whole of half of the face. The process involves the skin, subcutaneous connective tissue, and deeper structures, sometimes even the bone. It has been observed in connection with patches of morphœa.

Sclerema neonatorum is a disease of infancy, appearing usually at birth, consisting of a diffused stiffness and hardness of the cutaneous and subcutaneous tissues, accompanied by coldness, œdema, swelling, discoloration, lividity, and general circulatory disturbance. The disease is very rare, and is usually congenital. The skin assumes a glossy, reddish, or purplish, yellowish or brownish hue, and is firm or hard, rigid and tight. The surface is cold, and there is more or less œdema and infiltration. Rarely, spontaneous recovery sets in; the disease is, however, generally fatal. The cause is unknown. Microscopic examination of the skin shows the subcutaneous connective tissue to contain a "stearine-like deposit." The treatment should consist of stimulating measures, such as gentle friction, application of warmth, and oily inunctions.

Elephantiasis arabum is a chronic, hypertrophic disease of the skin and subcutaneous connective tissue characterized by enlargement and deformity of the part affected, accompanied by lymphangitis, swelling, œdema, thickening, induration, pigmentation, and papillary growth. It usually begins with erysipelatous inflammation accompanied by general febrile symptoms, the process being followed by slight permanent enlargement. The attacks recur, each time the enlargement becoming more marked, and later being followed by pigmentation and hypertrophy of the tissues. The legs and genitalia are the regions generally affected. The disease is found everywhere, but is most common in the tropics, about the line of the equator, especially in eastern countries. It is due to obstruction and inflammation of the lymphatics. Filariæ have been found in the blood of persons affected, and the parasite is thought by some to be the cause of the disease. Cases of enlargement of the scrotum, called "lymph scrotum," are also allied to the disease in question, and the chylous exudation of the former also contains filariæ.

The tissues on section are firm and of a whitish or yellowish color. The lesion consists of a hypertrophy of the connective tissue, chiefly of the subcutaneous connective tissue, stout fibres running in various directions, forming a dense network. The epidermis is often greatly developed, forming warty, papillary growths, while the bloodvessels and lymphatics of the corium are much enlarged. Where the process has continued for some time there are fatty degeneration and atrophy of the muscles, also enlargement of the bone. In well-marked cases, in which the disease has existed for a time, there is no difficulty about the diagnosis, and in the early stage repeated attacks of erysipelas about the limbs may indicate the nature of the process.

As for treatment, during an attack of erysipelas, rest, quinine, and iodide of potassium are indicated. After the inflammation has subsided, the rubber bandage should be closely applied. Where the scrotum is greatly involved, amputation is a comparatively safe method of treatment, much practised in China.

DERMATOLYSIS consists of a more or less circumscribed hypertrophy of the cutaneous and subcutaneous structures, characterized by softness, looseness of the skin, and a tendency to hang in folds. The skin and all its component parts are hypertrophied, including hairs, follicles, glands, and deeper structures. More or less pigmentation also exists. The disease usually attacks the back, face, and arms, also, rarely, the abdomen, genitalia, and thighs. The process is allied to molluscum fibrosum, the tissues being of a soft, fibrous, lipomatous character. The only treatment is with the knife.

REFLEX AURAL PHENOMENA FROM NASO-PHARYNGEAL CATARRH; OBJECTIVE NOISES IN AND FROM THE EAR.[1]

BY CHARLES H. BURNETT M.D.,
OF PHILADELPHIA.

IT has been known for some time that irritation in the nares, especially at the posterior parts, in the erectile tissue, would excite a spasmodic cough. It has of late seemed very plain to me, that certain aural phenomena, such as objective noises in and from the ear, could be explained in a similar way. The irritation in the nares and nasopharynx in these cases may be reflected to the muscular tissues of the velum palati, the fibres of the superior constrictor of the pharynx, or to the pterygoid muscles, inducing clonic spasms, which in turn produce snapping sounds, audible at greater or less distances from the patients. Thus, in the case of a Japanese officer, reported on page 443 of the first edition of my "Treatise on the Ear," an objective noise in the right ear was audible several feet from the patient, the nasopharynx and the pharynx were catarrhal, the opposite ear was affected with chronic purulent disease, and the ear from which the noise emanated had been the seat of an otorrhœa a year previous, and finally manifested symptoms of acute catarrh; the membrana tympani opened spontaneously, and mucus was discharged from it. Upon amelioration of the catarrhal disease in this case, the objective noises ceased. In this instance there was a marked spasm of the right half of the velum with the occurrence of each objective snapping sound in the ear. Spasms in the velum are the most usual visible manifestations in the muscular tissues near the ear, and have been noted by other observers in cases of similar objective aural noises.

Recently I have observed two other cases of objective aural noises, both of which were evidently connected with catarrhal disease in the nares and nasopharynx.

The first case was that of a young physician twenty-eight years old, who consulted me on October 5, 1883. He stated that for twenty months he had felt a "clicking" in his left ear, produced by both objective and subjective sounds, as, for example, the clicking of a card in the fingers, or the blowing of a shrill toy-whistle near his ear, or by his own coughing, speaking, or singing. It was found that when he said m, n, or o rather loudly, but with no other vowel sound, this "clicking" in his ear was produced. I thought I could detect a slight change in the pyramid of light, *i. e.*, a slight motion of the membrana tympani, when he produced the "clicking" in the ear by uttering these consonant and the vowel sounds; I also faintly heard, by means of the auscultation-tube, the "clicking" in his ear, when he produced it as described above.

There was no difference in this sound, when induced by subjective or objective causes; it was more likely to be produced at night or the end of the day when fatigued, than in the early part of the day. Up to this time it had never occurred automatically, *i. e.*, without an objective or a subjecto-objective excitant. Subsequently, when the patient was run down by the winter's work, this "clicking sound" did occur automatically, when he was entirely quiet.

The membrana tympani displayed a good lustre, and the pyramid of light was fair; the membrane was retracted, and the incus was visible. The membrane moved fairly under the pneumatic speculum. The right membrane manifested an identical condition. The Eustachian tubes were entirely pervious to inflations; the anterior and posterior nares were hypertrophic, the left markedly more so than the right; the pharynx was red, and manifested tobacco-smokers' pharyngitis. The patient had smoked cigarettes to excess, but had not done so recently.

There was at no time any discernible muscular spasm in any part of the pharynx, nor velum palati, nor was the patient conscious of any spasmodic motion or twitching in any part of the naso-pharyngo-aural tract.

Treatment.—The anterior, hypertrophied portions of both inferior turbinated bones were touched several times with Lugol's solution of iodine. Upon one occasion this mixture was pushed along the left inferior turbinated bone to the posterior pharyngeal wall. This caused pain and brought on an attack of the "clicking" in the left ear. The pain and the "clicking" were quickly allayed, however, by spraying the nostrils with fluid cosmoline (Petroleol). In a short time, *i. e.*, after four or five applications of the iodine to the inferior turbinated bones, and the use of the cosmoline spray, the hypertrophy became much less, and the noise in the ear occurred less readily and not so frequently. The patient then dropped all treatment until last spring, when the "clicking" became very annoying, occurring quickly when the patient was exposed to noises, or when he sang, talked, or whistled. Finally the noise occurred automatically even when the patient and his surroundings were perfectly quiet. The patient was somewhat debilitated, and, about this time, after running up stairs one evening after supper, fainted upon reaching his room.

[1] Read before the American Otological Society, July 15, 1884.

The nasal hypertrophies, both anterior and posterior, especially on the left side, seemed larger, and the nasal catarrh generally worse. Iodine and glycerine, equal parts, were applied to the hypertrophies, the nares were sprayed with Dobell's solution, and once the hypertrophied tissues at the back of the septum on the left side, were scarified by Dr. Seiler, by means of the galvanic wire-cautery. This treatment produced very good results, the "clicking" practically ceased to annoy, as it occurred very rarely, and only very faintly. The improvement has been maintained to the present time.

Etiology.—There was in this case an undoubted spasmodic action in muscular tissue near the Eustachian tube, but entirely invisible to the examiner, and not felt by the patient. I am disposed to locate this muscular spasm in this case, in the upper fibres of the superior constrictor of the pharynx. This muscle arises from the lower third of the margin of the internal pterygoid plate, and its hamular process, from the contiguous portions of the palate bone, and the reflected tendon of the tensor palati muscle, from the pterygo-maxillary ligament, from the alveolar process above the posterior extremity of the mylo-hyoid ridge, and by a few fibres from the side of the tongue in connection with the genio-hyo-glossus. Its superior fibres of insertion arch beneath the levator palati and the Eustachian tube.

The mucous membrane of this muscular tract was, as has been stated, markedly catarrhal, the inferior turbinated bones, and the nares were hypertrophied, and the fauces were affected by smokers' pharyngitis. In these conditions in the mucous membrane, there is found sufficient cause of irritation of the sensitive nerves in these parts; this irritation is reflected to the underlying muscular structures through motor nerves, and there ensue spasmodic twitchings near the Eustachian tube, which are perceived as subjective and objective noises.

That the origin of these "clickings" lay in the catarrhal condition of the upper pharynx and the nares, is freely shown by the cessation of noises upon the amelioration of the catarrhal symptoms.

The easy excitation of the spasms by talking is explained by the fact that a few fibres of origin of the superior constrictor of the pharynx arise from the genio-hyo-glossus, and hence lingual motions would tend to excite the aforesaid sounds in the ear. It may also depend upon the motions of the jaw, as the constrictor has a partial origin from the posterior part of the alveolar process, and also upon the movements of the buccinator, which has a common origin with the superior constrictor of the pharynx, in the pterygo-maxillary ligament.

The annoying audibility of these muscular spasms is due to the insertion of the superior constrictor near the Eustachian tube.

Another case, of objective snapping noises in the ear, came under my observation within a short time, and is now under treatment.

Miss McG., aged twenty years, stated on June 2, 1884, that about six months previous she had first noticed a clicking sound in her right ear, and that her family noticed that they, too, could hear it. She is not disturbed by the noise at night, though it appears to be almost ceaseless. Its occurrence is paroxysmal, with short intervals. It is heard objectively quite as well, perhaps better, at the nostrils than at the meatus of the right ear. It is very well heard at the latter point by means of the ear-trumpet. The number of "clicks" is about eighteen or twenty per minute. With each clicking sound the lower maxilla is both felt and seen to move, chiefly toward the right side; the latter symptom is very annoying to the patient. A manometric column attached to the right ear, rises and falls with each "click," due very probably, however, to the motion of the lower maxilla, and not to movements in the membrana tympani.

The patient stated that she had of late begun to hear the noise in the left ear. Objectively it is not very pronounced on this side. It can be heard, however, at this point. Pressure upon the muscles over the carotid on the right side, behind the angle of the jaw, arrests the motion of the latter, and the objective noise. Opening the mouth very widely, stops the noise almost entirely, only a faint "click" being heard now and then.

The patient is a pale blonde, somewhat neurasthenic; the right membrana tympani is opaque and retracted, and on this side the hearing is reduced to a few inches. The nares, nasopharynx, and fauces are catarrhal, and she feels often the dropping of mucus from her nasopharynx into the throat. Her spirits are not depressed by these peculiar aural phenomena, and she sleeps well. The motion of the lower maxilla, observed in this case, in connection with each clicking sound, is due to a clonic spasm of the pterygoid muscles of both sides; but chiefly of the left side, as denoted in the greater tendency of the maxilla to move towards the opposite side, *i. e.*, toward the right, since when the external pterygoid muscle of one side acts either alone, or chiefly, the corresponding side of the jaw remains fixed, and the symphysis deviates to the opposite side.

The distinct, objective audibility of the spasms at the nares and auditory meatus is due to the fact that the internal pterygoid arises from the pterygoid fossa, its fibres being attached to the inner surface of the external pterygoid plate, and to the grooved surface of the tuberosity of the palate bone. Its internal surface is in close relation to the tensor palati, while the external pterygoid arises from the pterygoid ridge on the wing of the sphenoid, and the portion of the bone included between it and the base of the pterygoid process and from the outer surface of the external pterygoid plate, and from the tuberosity of the palate and superior maxillary bones. Hence any vibration occurring in the muscular structures near these points of origin would be easily communicated by the Eustachian tube to the tympanic cavity and the external ear, and also directly through the nares to the external air. So that a snapping sound occurring in the region of these muscles would be at once a subjective and an objective noise in and from the nasopharynx and ear. These sounds may have been augmented by a simultaneous spasm in the fibres of the superior constrictor of the pharynx, which has a small tract of insertion on the inferior

maxilla, above the inner end of the mylo-hyoid ridge.

The spasms in the muscles in this case are to be accounted for, as in the previous instance, by the catarrhal irritation conveyed to the sensitive nerves of the mucous membrane in the vicinity of the muscles affected. The irritation is thence reflected to the motor nerves of the muscles in the catarrhal tract, and the latter, in an endeavor to eject the irritant, are thrown into a series of clonic spasms.

That these clonic spasms in the muscular structures of the nasopharynx, and the consequent snapping sounds, are produced by catarrhal irritation in the mucous membrane of the implicated muscular tract, is further proven by the cessation of the noises as soon as treatment has benefited the catarrhal state of the nasopharynx and nares. So far as the writer is aware, this is the first suggestion to quell these objective snapping noises in the ear by curing the nasopharyngeal catarrh, which very evidently underlies them as a reflex cause.

CHRONIC ARTICULAR OSTEITIS OF THE KNEE-JOINT, AND DESCRIPTION OF A NEW MECHANICAL SPLINT.[1]

By A. SYDNEY ROBERTS, M.D.,

Surgeon to the Philadelphia Hospital, Instructor in Orthopædic Surgery in the Medical Department of the University of Pennsylvania.

I have chosen the term Chronic Articular Osteitis as the one best expressing the pathological condition found in those lesions of the epiphyses of the knee-joint that have usually been described by the older writers under the caption "tumor albus." My reason for so doing has been by proper classification to refer directly to inflammation of the cancellous structure of bone, thereby avoiding the confusion that usually exists if the more general terms arthritis and knee-joint disease be employed.

Before considering the main feature of the paper, viz., to bring before your notice a new mechanical splint, designed for the treatment of chronic articular osteitis of the knee-joint; it may be profitable to review hastily the etiology and pathology of the affection, the latter especially in reference to its clinical expression, a thorough appreciation of which aids so materially in deciding upon an intelligent method of treatment.

From an analysis of many hundred cases of articular osteitis, I feel safe in asserting that two structures only are responsible for the development of chronic osteitis.

1st. The cancellous structure of the epiphyses.

2d. The synovial membrane.

Frequently the two are combined, and disease of either may develop from the other; it is not, however, until the cartilages and ligaments have been invaded by the inflammatory process that we are justified in using the term Arthritis.

The pathological changes that give rise to the more familiar clinical symptoms, may be classified in the following order:

A simple non-suppurative osteitis interna, the primary lesion in the more formidable osteitis interna fungiosa, caseosa, or necrotica, accompanying which suppuration or the formation of inflammatory neoplasia frequently adds serious complications to the process of cicatrization.

Of these and the many other subdivisions of chronic articular lesions designated by different pathologists, only two demand special consideration—the fungoid and suppurative, to which we may add the non-humid variety of old age, the "caries sicca" of Billroth.

In all save the necrotic variety, the process of destruction is by molecular death and absorption, or suppuration; the character of the discharge frequently marking the atonic form of the lesion.

The fungous proliferations of a chronic synovitis may, from pressure, eat their way through the cartilage and produce by contiguity an osteitis superficialis; traumatism, by direct injury to the articular surfaces, may produce the same inflammatory process; seldom, however, without a predisposition to the strumous, tuberculous, or rheumatic diathesis.

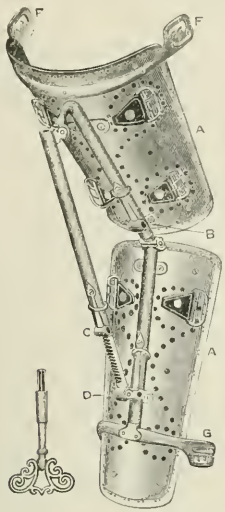
Any of these inflammatory conditions when existing in the epiphyses, give rise to certain neural disturbances that aid materially in their recognition. I refer to the ever-present symptom of rigidity of the joint due to a reflex spasm of the muscles that control it. This interference with normal joint-motion is due to an inflammatory irritation of the nerves distributed through the epiphyses, reflected by their centripetal fibres to the multipolar cells, thence to the great nerve-centres causing the apprehensive condition of pain, and the reflex spasm and consequent atrophy of the muscles controlling the articulation. It is to this involuntary muscular spasm that we are indebted alike for a means of differentiating true osteitis from many of the diseases that simulate it, as well as the insidiously progressive character of the deformity, *i. e.*, flexion of the limb and the frequent subluxation of the head of the tibia into the popliteal space. Accept what definition we may of the lesions found in post-mortem examinations of the joints, the progressive character of the disease, the tendency it presents to frequent exacerbations after long periods of repose, the difficulty in controlling deformity and of relieving pain, the frequent formation of cold abscesses, all class their treatment among the most difficult problems that may fall to the lot of a general surgeon. To meet the universally recognized principles of treatment, *i. e.*, fixation of the joint and extension, I have designed the splint that I now feel justified, from the success that has attended its use, in presenting to the profession.

It consists of two light padded steel troughs (A A) that are firmly secured to the limb by encircling bands of surgical webbing, affording absolute fixation to the joint when the extending rods are locked after adjustment. Three ratchet extension bars arranged in the form of a triangle are placed posteriorly, corresponding to the long axis of the limb, placing within the control of the surgeon a power that will overcome the flexion and the tendency to the production of de-

[1] Read before the Medical Society of the State of Pennsylvania, Philadelphia, May, 1884.

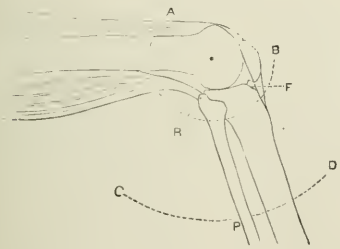
formity, and at the same time produce extension. It will be noticed, in referring to the accompanying cut, that the extension rod "B" acts directly upon the head of the tibia and parallel with the line of con-

FIG. 1.



traction of the flexor group of muscles, obviating thereby the error in the mechanical arrangement of the popular Stromeyer's splint, or in all where the power is applied low down on the tibia to overcome

FIG 2.



the flexion. Reference to Fig. 2 will illustrate diagrammatically the point at issue, *i. e.*, how to overcome the flexion and subluxation without establishing a fulcrum (F) at the surface of the diseased joint, which would be the case should we apply our force at (P) a distance below the insertion (R) of the resisting flexor tendons.

In the splint under consideration, the long extension rod "C" it used only as a compensating bar, adjusting the angle of the splint to the angle of the flexion of the limb. The power for restoring the head of the tibia, and overcoming the spasmodic contraction of the flexor muscles is applied directly in the axis of their contraction. Through the extension bar "B" (Fig. 1) the head of the bone describes in its restoration the arc of a circle, A-B (Fig. 2). The compensating bar in correcting the angle or flexion carries the limb through the arc C-D having a centre in the end of the femur. Mechanically this arrangement of force corrects the deformity and relieves, by extension, the reflex spasm of the flexor muscles without crowding together the diseased joint-surfaces or aiding in subluxating the head of the tibia, as would be the case should the limb proper be used as the long arm of our lever with the insertion of the hamstring tendons, instead of the normal centre of motion of the joint as the centre of motion of the splint. Supplementing the direct extension upon the contracted muscles, another bar ("D") has been added to aid in steadying the joint and relieving interarticular pressure. Its action upon the limb is produced through adhesive plaster applied above and below the joint, to which surgical webbing has been attached. This is firmly secured to the counter-extending band "F," and to the extension rod "G," affording a means of direct extension always corresponding to the angle of flexion. The extension bars are controlled by a key and ratchet movement held in place after adjustment by a small ring and pin. I have found that this method of securing fixation with extension by a portable appliance enables the patient to enjoy, by means of crutches, all the hygienic advantages of open air and exercise, facilitating thereby a better result than would otherwise be obtained.

MEDICAL PROGRESS.

FEMORAL HERNIA; PERFORATION OF A DIVERTICULUM.—At the recent German Surgical Congress, DR. BUSCH, of Berlin, described the case of a man, aged fifty-three, who had for years worn a truss on account of a small femoral hernia on the right side; this gave him no inconvenience and could readily be replaced. At the beginning of April he was seized with severe pains; he reduced the hernia, which appears to have increased in size, and the pain immediately increased, and severe peritonitis and distention of the abdomen followed. The patient was admitted into the hospital almost moribund, and nothing could be felt in the right femoral region excepting a slight thickening of the tissues. Enemata of lukewarm water were administered, but the patient died within five hours after admission. At the necropsy, the peritoneal cavity was found to be filled with feces; on the right side was the sac of a femoral hernia completely empty. A small diverticulum projected from the small intestine, two feet and a half above the cæcum; it was not gangrenous, but at its base a small perforation was detected. Dr. Busch believes that the diverticulum had probably occupied the hernial sac, and had become ulcerated through pressure of the structures surrounding the neck of the sac, hence the extravasation of feces and the disastrous results that followed the reduction of the hernia. The diverticulum was exhibited at the meeting of the Congress.—*British Med. Journ.*, June 14, 1884.

Gangrene after Subcutaneous Arterial Wound.—Dr. C. Juengst, of Heidelberg, in addition to a case of this kind published by Weitz in the *Berlin. klin. Wochens.*, No. 7, 1884 (see *Amer. Journ. Med. Sci.*, April, 1884, p. 593), reports two similar cases, which seem noteworthy from the fact that the gangrene occurred after an isolated wound of the arterial intima.

A young man, æt. 19 years, sustained a simple fracture of the right forearm in the lower third. The patient did very well until the fourth day, when it was found that there were slight troubles of sensibility, and that the skin was slightly discolored. On the fifth day the fingers and hand were completely anæsthetic and anæmic: above the seat of fracture the skin and sensibility were normal. On the sixth day, the condition being no better, it was determined to amputate between the upper and middle third. Examination of the amputated part showed that the radial and ulnar arteries were sound, while the brachial artery contained a thrombosis in the upper amputated surface. Further examination showed that the intima was ruptured almost half way around the circumference, but the media and adventitia were uninjured.

A young man, æt. 20 years, received a severe wound upon the left knee. A few hours later the lower third of the thigh, the region around the joint, and the upper two-thirds of the leg were greatly swollen, the skin stretched tense and elastic by the blood effusion, and considerably blackened and excoriated. There was abnormal mobility of the knee-joint, with slight crepitation. The pulse in the right posterior tibial and dorsalis pedis arteries was normal, but could not be felt on the left side; and the left foot was cool and anæmic, though sensibility and motion were about normal. On the next day the foot was discolored, and, although warm, no arterial pulse could be felt. On the third day sensibility in the foot was lost. After a few days more, bullæ began to form on the now painful, partly reddened and partly livid leg, and the general temperature rose. On the eighth day the limb was amputated above the knee. Examination of the amputated portion showed that the knee-joint was full of serous effusion, the capsular ligament completely torn through, and the internal condyle of the tibia shattered, as well as the head of the fibula. In the popliteal artery a rupture of the media and intima, about one inch above the bifurcation, and a thrombus had occluded the vessel at this point. The peripheral part of the artery was completely bloodless, as was the popliteal vein above the wound, it also containing a thrombus, although there was no rupture of its coats.

These cases are noteworthy from the fact that gangrene of the arm and leg was caused by an isolated injury of the intima of the principal arteries, and without involving the other arteries. In the first case this was a simple tear, produced probably by overstretching of the vessel. Whilst in the second case the severity of the traumatism, and the cold and anæmic condition foreboded the result, these symptoms were absent in the first case, in which there were never any symptoms of elbow-joint injury until the limb was examined after amputation. The absence of pain and swelling in the joint, and the situation of the lesion—the lower third of the forearm, rather precluded the diagnosis or even suspicion of injury to the joint. And it was not until four days after the injury that there were any evidences of circulatory arrest. These cases, and the one reported by Weitz, are, therefore, of unusual interest, as showing how easily a simple fracture may be the indirect cause of gangrene, and what time may elapse after the injury before symptoms of circulatory arrest set in.—*Berliner klin. Wochenschr.*, April 14, 1884.

Dermatolysis or Pachydermatocele—Fibroma Molluscum.—Surgeon-Major D. F. Keegan reports the case of a Hindoo, æt. forty years, who came under his care in the Indore Charitable Hospital. On being examined the whole of his body was found studded over with fibroma molluscum, varying in size from a pea to a walnut. In addition to the numerous fibromata, he was found to be the subject of a huge pachydermatocele or dermatolysis, which sprung from the left mammary region and hung down along his side, reaching to the level of the left great trochanter of the femur. When the patient walked briskly this pendulous tumor swayed backwards and forwards, and it could be taken in the hand and laid on the supraclavicular region. For years this tumor had caused him much inconvenience by its weight and size. The only portions of his body found to be free from the smaller fibromata were the soles of his feet and the palms of his hands. Up to his tenth year he was quite free from any tumors of the skin, and then for the first time he remarked the existence of a small tumor of about the size of a pea, growing about two inches posteriorly to the left mamma. This tumor has steadily grown for the last thirty years, and has at last become so inconvenient from its weight, size, and position, that he finds much difficulty in doing his work. During all these years the greater portion of the integument of his body has been invaded by fibromata. He further states that his mother had a similar tumor of about half the size of his own, and that it grew in the same situation.

The tumor springs from the level of the left mamma and hangs down as far as the left great trochanter of the femur. Its base or pedicle measures five inches in width and nine inches in girth or circumference. The length of the tumor from base or pedicle to its most dependent point is twelve inches, and the circumference of the tumor at its thickest portion measures fourteen inches. The tumor consists of a lax outgrowth of connective tissue, and feels like a long, loose bag of integument, which can be separated on pulling it out from opposite directions, and the looseness of the contained areolar tissue allows the inner walls of the tumor to be rolled one upon the other. The tumor on being grasped between the fingers gives arterial pulsations, showing that it is well supplied with blood. The surface presents the main characters of normal integument somewhat thickened, and the skin follicles are very distinctly marked. Cuticular sensibility is slightly diminished over the tumor. It has never shown any tendency to ulcerate at any point, although it has often been torn by thorns and brambles when the patient was working in the fields.

Dr. Keegan determined to remove the tumor.

Chloroform having been administered and the base or pedicle of the tumor having been secured by a broad clamp, the pachydermatocele was removed with one sweep of a long catlin. It was found necessary to

twist several large vessels, and the actual cautery was passed over the line of incision. Very little blood was lost, and he made a good recovery. The weight of the tumor on being removed was found to be two pounds and six ounces, and consisted of thickened integument and areolar or connective tissue well supplied with numerous bloodvessels.

He places this case on record not on account of any surgical importance it may possess, but with a view of proving that the disease which Valentine Mott called pachydermatocele, and other authors call dermatolysis, is only an exaggerated form of fibroma molluscum. Certain it is that this disease bears a very close relation to fibroma, for here we find the two diseases associated in the same patient.—*Indian Med. Gazette*, April, 1884.

Cider and Stone in the Bladder.—According to Dr. Dennis Dumont, stone in the bladder is almost unknown in Normandy, which he attributes to the use of cider in place of wine or beer. In a report on the subject he asserts that during nineteen years' practice in the hospital at Caen he had only four cases of stone in the bladder, in three of which wine was the habitual drink of the patients. A further inquiry having been instituted, it was ascertained that at Bayeux and Falaise, in the Department of the Manche and the Orne, the rarity of stone in the bladder in these regions is attributable to the use of cider, and to a diet containing less nitrogenous substances than that generally adopted in the other provinces, notwithstanding the abundance and cheapness of meat. Cider is therefore considered an excellent remedy for gravel, obesity, and certain forms of gastritis.—*Lancet*, June 14, 1884.

Needle-swallowing.—A. Wide reports (*Upsala Läkareför. Förhandlingar*, 1884, Bd. xix. Hft. 2), under the above title, a case similar to the one recorded by Albert in his work on surgery, in which Otto, of Copenhagen, removed, at various times, three hundred and ninety-five needles from the body of one patient.

Wide's patient was a young woman of twenty-three years, strong, but of phthisical family. In 1876 she had acute rheumatism, and was four months in the hospital. With the exception of rheumatoid pains in the limbs and stitch-like pains in the cardiac region, she became well, and remained so until early in 1882, when attacks of faintness, headache, and pains in the joints, palpitation of the heart, and shortness of breath troubled her. In the summer of 1882 she had symptoms of gastro-intestinal catarrh, and in August had an attack of stiffness in the back and legs, so that she could not get out of bed without help. There seemed to be nothing wrong about the thoracic or abdominal organs. In November, 1882, obstinate vomiting came on, not connected with the time of eating, obstinate constipation, pains in the abdomen, and hypersensitiveness of the cæcal region. After that, she had an attack of tonic cramps, and, following that, had left hemiplegia and hemianæsthesia, so that a diagnosis of hysteria was made. From May until June, 1883, there were attacks of painful vomiting, with diarrhœa. There were sharp pains in the right knee and left arm, as well as in other parts of the body, and a small abscess formed on the inner side of the knee, which, on being opened, was found to contain a needle. In other parts of the body there were seen bluish-red, painful elevations of the skin, in every one of which a needle was felt. The patient was chloroformed, and from the arms, legs, and skin of the thorax and abdomen twelve and a half needles were removed.

The patient then stated that in May, 1881, she had swallowed five and a half packages of needles, each package containing twenty-five needles, in order to commit suicide. She had swallowed them with the eye-end forwards, and generally enclosed in paper. She finished the five and a half packages in two weeks. There were no pains for several weeks, and defecation was never painful; nor had any of the needles passed in the stools. Subsequently, at nineteen different times, sixty-five whole and six half needles were removed. By January, 1884, thirty-one more were removed, and in January, eleven, so that up to the time of the writing, one hundred and ten needles had been found. By this time the patient had become hysterical again, and at Christmas swallowed five packages, four of which contained more than twelve needles each. Wide concludes his article by mentioning a case recorded by Herholdt, in which three hundred and eighty-nine needles were swallowed.—*Centralbl. für Chirurgie*, May 24, 1884.

Deafness in Syphilitic Tabes.—Dr. P. Hermet, in an article on this subject, draws the following conclusions:

1. Deafness in syphilitic tabes is due to a deep lesion.
2. Its evolution is very rapid, and it may be considered as a symptom of the preataxic period.
3. It is an element in making a diagnosis, and when one observes sudden deafness in a syphilitic, without apparent lesion, other symptoms of locomotor ataxia should be carefully looked for.—*L'Union Méd.*, June 14, 1884.

Iodoform in Erysipelas.—Mr. C. Clark Burman calls attention to the value of iodoform in collodion (℥j to f℥x) as an application for erysipelas. The heat and pain quickly disappear, and the swelling rapidly subsides. Furthermore, there is a remarkable freedom from irritation during the period of desquamation. Mr. Burman reports four very successful cases.—*Practitioner*, May, 1884.

Extirpation of the Kidney.—At a recent surgical clinic, Professor Billroth presented a kidney which he had removed on the previous day, and made some general remarks on total extirpation of the kidney.

The patient was a male, about thirty years old, who first presented symptoms of kidney trouble eighteen months ago—pain in the back, etc. Later, a tumor developed under the free border of the ribs, and was somewhat movable. The nature of this tumor was quite obscure; the fever, which seemed to be associated with its growth, pointed to a perinephric process. Echinococcus was excluded on account of the rapid growth of the tumor, and since there was scarcely any fluctuation. Three months ago the patient asked for an operation for the removal of the tumor, but he was so strong, and in such good general health, that Billroth hesitated to operate. A bandage was put on, in order to fix the tumor and lessen the pain, but it soon became painful by the pressure.

Four weeks ago, a new difficulty arose. The pain in

creased, the legs suddenly swelled, and it was found that both femoral veins were thrombotic. It was difficult to conceive how this could have occurred. Compression of the vena cava by the tumor was thought of. Billroth now believed that the thrombi would break down, and cause death. But, curiously enough, the thrombi were completely loosened in two or three weeks, and the œdema completely disappeared. How this loosening of the fibrin-clot occurred, whether in small molecules or in mucous forms, is uncertain. Billroth inclines to the latter hypothesis, since we very often see in wounds such thread-like masses which come from loosened thrombi.

After the tumor and ascites disappeared, the tumor could be again examined. It had become about one-half larger. It could not be a chronic inflammatory process, but most probably a tumor connected with the kidney. The urine was normal. But it was not, therefore, a foregone conclusion that the tumor was malignant, although the chances seemed to be that it was malignant. It was, therefore, determined to extirpate the kidney. The upper fourth of the kidney was healthy, but the lower three-fourths were enlarged by malignant growth. The patient rallied well from the operation, and was doing well on the second day.—*Allg. Wien. med. Zeitung*, May 13, 1884.

ADMINISTRATION OF PARALDEHYDE.—DR. KERAVAL gives the following as the most convenient formulæ for the administration of paraldehyde:

For internal use—Paraldehyde f℥j, distilled water and some aromatic syrup (mint or vanilla) āā f℥j. For rectal administration—Paraldehyde f℥j, marshmallow water f℥v, one yolk of egg. For hypodermatic use—Distilled water f℥ss, cherry-laurel water and paraldehyde āā f℥j. This should always be warmed before injection, as otherwise the paraldehyde may crystallize.

The following have been found to be useful formulæ:

℞.—Paraldehyde, . . . f℥vj.
Essence of peppermint, . . gtt v.
Olive oil, ... q. s. ad f℥jss.—M.

℞.—Paraldehyde, . . . f℥ss–j.
Tinct. bitter orange peel, . f℥ij–iv.
Distilled water, . . . q. s. ad f℥iv.—M.

℞.—Paraldehyde, . . . f℥iv.
Alcohol (90°), . . . f℥ijss.
Simple syrup, . . . f℥ij.
Tinct. vanilla, . . . f℥j.—M.

℞.—Paraldehyde, . . . ♏xv–f℥j.
Boiling water, . . . f℥j,
Simple syrup, . . . f℥ij.
Tinct. vanilla, . . . q. s.—M.

[The dose of paraldehyde for an adult is from ♏xv to f℥j or more.]—*Progrès Médicale*, June 14, 1884.

THE VASO-MOTOR NERVES.—MM. VON ANREP and CYBULSKI draw the following conclusions from experiments made in the laboratory of Prof. Tarchanow, in St. Petersburg:

1. No analogy exists between the vagi and the vaso-dilator nerves, as regards the action of atropine.

2. Furthermore, there is no analogy between the vaso-constrictor nerves and the accelerator nerves of the heart. It is well known that a maximum irritation of the accelerators is powerless to overcome the effect of a minimum irritation of the vagus.

3. A certain blood-impression is a condition *sine qua non* for a perceptible dilatation of the vessels.

4. The period of slow irritation of the vaso-dilator, as well as of the vaso-constrictor nerves of the tongue, and also the height of the waves for the same number of induction-beats and the maximum wave-heights are closely related.

5. Consequently, there is no essential difference between the two sorts of vaso-motor nerves. It may, then, be admitted that there exist in the vascular walls two complicated nervous autonomies, one causing constriction, the other dilatation.—*Gaz. Hebdomadaire*, June 3, 1884.

ESSENTIAL ASCITES.—DR. TOULZE has recently made this the subject of an inaugural essay. Essential ascites, he says, is a rare disease, though there are cases which are undoubtedly examples of idiopathic ascites. It is a disease which has a special etiology, symptomatology, and treatment. While sympathetic ascites is rarely curable, idiopathic ascites is almost always curable after a longer or shorter time—generally after one puncture; several punctures are rarely necessary.

The diagnosis is very difficult, and should be made only after very careful examination. As to treatment, diuretics should be used at first, either the nitrate or acetate of potash, given in some preparation of triticum repens, or juniperus communis, or digitalis in some form may be administered. If these do not have the desired effect, drastic purgatives may be used, and preferably the resinous purgatives. If, in spite of internal medication, the fluid continues to accumulate, puncture must be resorted to.—*Revue de Thérap.*, June 15, 1884.

SPLENECTOMY.—At the meeting of the Société de Chirurgie, on June 11, 1884, M. TERRIER reported a case of splenectomy recently performed on a young girl for splenic hypertrophy and leucocytosis, there being one white in two hundred and sixty-three red globules of the blood. The patient died of slow internal hemorrhage in twenty-four hours, the hemorrhage being entirely from capillary vessels. This case confirms the precept that increase of the white globules is a contra-indication to surgical operations; although Franzolini performed this operation successfully when there was one white globule to thirty red.—*Gaz. Hebdom.*, June 27, 1884.

VAGINAL EXTIRPATION OF THE CANCEROUS UTERUS; NEPHRECTOMY.—At the meeting of the Société de Chirurgie, on June 4th, M. BŒCKEL reported a case of cancer of the uterus, operated on by vaginal hysterectomy, in October, 1882, and the uterus removed. From this the patient recovered, but with a ureteral fistula, one of the ureters having been caught in the teeth of a pair of hæmostatic forceps. Bœckel saw no remedy for this except nephrectomy, which he performed one month after the first operation. The patient recovered, and left the hospital in three weeks, but died seven months afterwards from degeneration (cancerous?) of the abdominal glands.—*Journal de Méd. de Paris*, June 14, 1884.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, JULY 26, 1884.

THE PREVENTION OF CHOLERA.

THE International Sanitary Conference of 1874 unanimously affirmed that "the Asiatic cholera, susceptible of epidemic extension, is not developed spontaneously, except in India, and when it appears in other countries it is invariably by introduction from without." The evidence of the truth of this conclusion is overwhelming and decisive, and is admitted, we believe, by all medical men and sanitarians who have given the subject any serious thought. Moreover, when cholera spreads to other parts of the world it invariably follows the lines of travel, and it has never appeared in America unless Europe has been first affected.

With these facts before us, there is abundant evidence to prove that two things are absolutely necessary to prevent the introduction of the disease into our country, viz., *quarantine and municipal cleanliness*—by quarantine we mean such detention as will positively insure a clean ship and cargo, with non-infected passengers and baggage.

How best to secure these results are the only questions with which we have now to deal. The Government has taken the initiative by requiring the consular officers abroad to have all vessels bound to the United States thoroughly inspected before sailing, whether from infected ports or otherwise; to refuse clean bills of health, unless so inspected, and to give timely notification by cable of the progress of the disease, and of the departure of any suspicious vessel or of emigrants from the infected districts for our shores. As a further security, the Revenue Cutter Service has been placed on guard to intercept all vessels coming to this country, and to ascertain not only whether they have clean bills of health, but also to learn whether any disease has appeared on board since they left the other side, and if they are in a good sanitary condition. The Treasury Department has also temporarily interdicted the importation of rags from all countries infected or supposed to be infected. Government quarantine stations, under the management of the Marine-Hospital Service, are now open at Ship Island, Miss., Sapelo, Ga., and between the Capes in Chesapeake Bay, for the refuge of infected vessels, and the care of their diseased passengers and crews.

Quarantine, which includes disinfection, and all the procedures necessary to change an infected ship into a clean and healthy one, requires that the sick be removed to isolated hospitals, the well to comfortable barracks for observation; and the luggage of sick and well to be removed and subjected to thorough disinfection. The cargo to be discharged upon lighters, or removed to warehouses, exposed to the air, and disinfected if practicable, or destroyed if not—as in the case of fruits, etc., the vessel to be then thoroughly disinfected by the most approved methods, first having been washed out and cleansed; it is then ready to go to its dock.

Municipal cleanliness includes house-to-house inspection—back-yards, water-closets, cellars, cesspools, and out-of-the-way places, should receive particular attention—the streets, market-houses and surroundings, must be kept clean; school-houses, factories, and other large establishments and their inmates should be included; the water-supply should be examined, and water boiled before using if found to be impure; well-water is particularly dangerous on account of its liability to receive the over-flow from storm-water or from seepage, and reservoirs are not less dangerous if located so as to receive the washings from hill-sides or ravines; water-closets and sewers should be flushed with abundance of water, the former daily, the latter two or three times a week. In the country stagnant pools must be drained, out-houses, pig-pens, and the like, kept clean, and privies disinfected daily. Personal cleanliness must be maintained, and the diet must be wholesome—fruits, if imported, should be carefully washed or peeled, and over-ripe or green fruits rejected.

OPERATIVE INTERFERENCE IN STRICTURES OF THE ŒSOPHAGUS.

THE treatment of carcinomatous and cicatricial strictures of the œsophagus by incision or the establishment of a fistula in the neck or the abdomen has attracted not a little attention during the past year, the most noteworthy papers that have appeared on the subject being those of Alsberg, Blum, Fiedler, Vitringa, and S. W. Gross on gastrostomy, that of Sands on internal œsophagotomy, and an elaborate article on gastrostomy, œsophagostomy, internal œsophagotomy, combined œsophagotomy, œsopha-

gectomy, and retrograde divulsion, contributed by Dr. S. W. GROSS to the July number of the *American Journal of the Medical Sciences*. An analysis of the merits of the operation in the light of the latest statistics collected by Dr. Gross will doubtless prove acceptable to our readers, since which is the best method of treating these cases is still *sub judice* and will be discussed in the Section of Surgery at the forthcoming International Congress at Copenhagen.

Omitting œsophagectomy, which can rarely be called for, the operations applicable to carcinomatous stricture are gastrostomy, œsophagostomy, and internal œsophagotomy. Of 167 gastrostomies, 49, or 29.34 per cent., perished as the direct or indirect result of the procedure, while 66 died of exhaustion, inanition, or extension of the disease, at periods varying from nine hours to one month, 32 having expired within twenty-four hours from the tardy resort to the procedure. Of the 46 that were known to have lived upwards of one month, 28 expired subsequently in from five weeks to ten months, while 18 were still alive at periods varying from one month to thirteen months. The average duration of life for all cases after the stomach was opened was 33 days.

Of 21 œsophagostomies, 12, or 57.14 per cent., died as the result of the procedure, while 5 perished from exhaustion. The 4 survivors lived for periods which varied from two to sixteen months, while the average life for all cases was forty-six days. In 4 of the fatal cases death was occasioned by the improper use of dilating bougies or tubes used for feeding.

Internal œsophagotomy was practised only once, but five distinct operations, supplemented by methodical dilatation, were required to keep the patient alive for six months.

From the foregoing data, Dr. Gross concludes that gastrostomy has proved to be the simplest, most rational, and safest of the operations for the relief of carcinomatous stricture. Increasing experience demonstrates that the results are growing better and better, which cannot be said of œsophagostomy; and there is every reason to believe that the successes will become more numerous if it is resorted to as soon as the diagnosis of the disease has been made, and before the powers of the patient are materially impaired. The procedure itself requires no special skill for its performance, and the subsequent treatment may be entrusted to the patient himself. In not a few cases, by affording rest to the parts, the spasm, swelling, and pain disappear, and the subject is enabled to swallow with comparative ease.

The same operations, with the addition of combined œsophagotomy and retrograde divulsion, are applicable to cicatricial stricture. Of 37 gastrostomies, 11, or 29.72 per cent., perished as the direct or indirect result of the procedure, and 9 died, at periods varying from thirty hours to twenty-eight days, from exhaustion, starvation, or other causes. Of the 17 survivors, for upwards of one month, the precise duration of life is known in 16. Of these 9 died subsequently in from two to forty-eight months, while 7 were living at periods varying from four months and a half to fifty-six months. The average duration of life for all cases after the stomach was opened was two hundred and ninety-five days.

Of 5 œsophagostomies all proved fatal, the average duration of life having been forty days. In 1, the passage of the bougie produced a deep-seated abscess, and in 3 the opening was made above, instead of below the stricture.

Of 18 cases of internal œsophagotomy, 6, or 33.3 per cent., perished as the result of the procedure within sixteen days. Of the 12 survivors 9 were living at periods varying from one month to seven years, but 6 cases required a repetition of the operation. The average life for all cases was two hundred and forty-six days.

Of 5 combined œsophagotomies, 2, or 40 per cent., perished, while the remaining cases were alive, respectively, at the end of three, twelve, and eighteen months, but the condition of one was unsatisfactory.

Of the three retrograde divulsions, in the hands of Loreta, all were successful, but as less than four weeks had elapsed at the date of the reports, the value of the procedure must remain undetermined.

Divulsion through an opening in the stomach is only applicable to strictures near the cardia of the adult, and combined œsophagotomy for obstruction in the same locality should be reserved for children. Hence, these procedures are of limited applicability.

In estimating the comparative value of the other operations for cicatricial stricture, Dr. Gross concludes that internal œsophagotomy, if performed at all, should be done only for comparatively recent and short coarctations, that œsophagotomy should be practised when the incision can be made below the obstruction, and that gastrostomy is the best, safest, and most generally applicable of all.

SPERMATOZOA OR SPERMATOZOID.

THE subject of human generation has been of great interest from ancient times. For centuries the prevailing doctrine was that the male was the true creator, and the female furnished only the place and the means for the development of the new being. One of the most interesting cases illustrating this view, especially interesting in its medico-legal aspects, is found in Greek mythology; it is very well presented by Æschylus in the *Eumenides*.

It is not necessary to quote Æschylus, Aristotle, or other ancient authors to prove what great importance was attached to the male, and how little to the female in human generation. Harvey came, and his egg

doctrine for a while made the spermist's theory somewhat doubted. But in 1677, or about that time, Ham—who, according to Robin's researches, was neither a medical student nor a German, as many recent writers assert—found in the nocturnal emissions of a patient having gonorrhœa, animalcules with a tail. Here we cannot help calling attention to the great obligations which science was thus placed under to gonorrhœa. How long might she have waited for the important discovery of the essential agent of fecundation if this disease had not existed! However, since that discovery science has done a great deal for gonorrhœa, and therefore we may consider the debt of the former as more than liquidated.

But, resuming; the great microscopist, Leeuwenhoeck, had his attention called to the discovery by Ham, and from his own observations he declared that human sperm was filled with *parvulis puerulis*. Of course, then, if the babies were already in the spermatic fluid, all that was necessary would be for one of these to get into the uterus, to grow there into a perfectly developed fœtus. Apollo, who in the play referred to taught the spermatic theory of generation, if he had only had a microscope, could have done as well; the fact is, his doctrine as to generation was repeated by Leeuwenhoeck, except that the latter made the essential agent a minute part, instead of all the spermatic fluid.

It was very natural that these supposed animalcules thus discovered in the seventeenth century, should receive the name of spermatozoa, but now that their animalcular character is generally rejected, the retention of the name is a mistake, and they ought to be called spermatozoids.

So, too, the part which they play in impregnation has, in recent years, become better understood. All are familiar with the picture, so common in works on physiology and on obstetrics, of an ovum around which, or within which, so many of the so-called spermatozoa are found, more numerous than suitors in the palace at Ithaca. Then, too, we were taught that this hungry crowd lost their individuality, underwent solution, and impregnation resulted from the nucleus of the ovum being thus in a sort of warm spermatic infusion,—very much, we suppose, as some unfortunate maiden has been thought to have been impregnated by bathing in a stream or in a tub in which a man has recently had a seminal emission. But now it is known, from the study of impregnation in some of the inferior forms of animal life, that only one spermatozoid is concerned in the process. This fortunate one among the hundreds discharged by the male, thrusts its head into the ovule —its tail, a mere organ of propulsion, being no longer needed, is dropped off, just as our ape-like ancestors in the far-past ages lost their tails—and from this head the male pronucleus is formed, which fuses with the female pronucleus, and the process of conception is accomplished.

TENECTOMY IN PARALYTIC TALIPES CALCANEUS.

IN the *British Medical Journal* for June 14. MR. WALSHAM records four cases of paralytic talipes calcaneus, treated by excision of a portion of the tendo Achillis. In three of these the patients were discharged walking well, while in the fourth, progression was improved, but with the foot still slightly flat. From one-half to three-quarters of an inch of the elongated tendon was excised, the ends being cut obliquely in opposite directions, so that, when approximated, they overlapped splicewise for about three-fourths of an inch, and were secured in this position by kangaroo-tail-tendon ligatures, two of which were applied on each side. The foot was secured in a position of extension by Bavarian plaster or tin splints. The operations were done under antiseptic precautions, and there was slight suppuration in one case.

Mr. Willett has also resected the elongated tendo Achillis in paralytic calcaneus with good results, and there can be no doubt that the procedure has a promising future in cases in which the gastrocnemius and soleus muscles have not undergone advanced atrophy and fatty degeneration.

THE RIPENING OF CATARACT.

CASES not infrequently arise in which it is desirable to mature or ripen a cataract with a view to early operation. If both eyes are the seat of the affection, if only one good eye remains and its vision is becoming obscured by slowly progressing opacities of the lens, or if the patient is about to move to a locality where there is no skilled surgeon, the hastening of the process of maturation may relieve not only the sufferer, but, it may be, his family from great distress, and prevent years of blindness.

To accomplish this object, FOERSTER, of Breslau, makes a preliminary upward iridectomy, through which the lens falls forward and comes in contact with the posterior surface of the cornea. If the latter be gently rubbed with a hard, smooth substance, as a Daviel's silver curette, either in a circular direction or from the centre toward the periphery, the lens will become opaque in from four weeks to three months, or even within a few days, if it were partly opaque before the manipulations were begun.

Massage of the lens has been performed by Foerster upwards of two hundred times, without any inflammatory sequelæ, and he considers it devoid of great danger. His favorable experience is not, however, confirmed by the results obtained by NOYES and MITTENDORF, as published in the *Medical*

Record for August 4, 1883, and June 28, 1884. Thus, of 8 cases in the hands of the former operator, 2 had a severe iritis, while of 20 under the charge of the latter surgeon, there were serious complications in 3, leading in one to loss of the eye, and a mild form of iritis, with a few fine thread-like posterior synechiæ, in 8. The remainder did well, the process of healing having been short, and some of the patients having being able to leave their bed on the second day. These results, which are in such striking contrast with those obtained by Foerster, indicate that the procedure should be resorted to with great caution.

REVIEWS.

Eczema and its Management. By L. Duncan Bulkley, A.M., M.D., etc. Second edition. New York: G. P. Putnam's Sons. No date.

The present edition of Dr. Bulkley's admirable monograph differs in no essential degree from the first edition, issued a year or so ago. Some new statistical matter, a number of necessary typographical corrections, and a few words or sentences added here and there, are all that distinguish the present from the former issue. While, therefore, we would suggest that the owner of the old book need be in no hurry to exchange his possession for the new, we can most cordially recommend Dr. Bulkley's work to every practitioner of medicine who does not already own a copy. It is eminently practical, and the chapter on the management of infantile eczema alone, were it thoroughly mastered, would aid in the cure of many cases in which time only—under the ordinary management—can be expected to work amelioration.

A Handbook of Therapeutics. By Sydney Ringer, M.D., Professor of Principles and Practice of Medicine in University College, London. Tenth Edition. 8vo., pp. xl. 988. New York: William Wood & Co., 1883.

Dr. Ringer's admirable work has reached its tenth edition, an evidence of the regard with which it is considered by the profession. The book is abreast of the latest therapeutical discoveries, and an elaborate and useful analytical index, prepared by Dr. Maxwell, is added, compensating in some degree for the faulty arrangement of the subjects. A noteworthy feature of this edition is an excellent introductory treatise upon the various objective symptoms of disease, including notes on the tongue, pulse, skin, the temperature of health and of disease, fever, chronic fever, dropsy; followed by an exposition of the uses of various adjuvants to the pharmacopœia, such as baths, cold, warm, hot, shower, douche, and sponge; the Turkish bath; poultices; enemata, etc.

The whole forms a very complete treatise upon therapeutics, and, barring the imperfections of arrangement, is worthy of the highest commendation.

SOCIETY PROCEEDINGS.

AMERICAN OTOLOGICAL SOCIETY.

Seventeenth Annual Meeting, held at the Grand Hotel, Catskill Mountains, July 15, 1884.

(Specially reported for The Medical News.)

The annual meeting of the American Otological Society was held at the Grand Hotel, Catskill Mountains, N. Y., on Tuesday, July 15, at 10.30 A.M. In the absence of the President, Dr. C. H. Burnett, of Philadelphia, the Vice-President, Dr. J. S. Prout, occupied the Chair.

Twenty-three members were present at the meeting, and three new members were elected.

After the usual routine business, the papers on the bulletin presented by the Business Committee were taken up in the following order.

Dr. H. Knapp, of New York, presented a paper on

THE INDICATIONS FOR OPENING THE MASTOID PROCESS, BASED ON SOME RECENT OBSERVATIONS.

The writer referred to the discussion on the same subject at the meeting of the Society the preceding year, which went to show a greater amount of diversity of opinion among the members than the accumulated experience seemed to warrant. On the part of a majority of the members, more scepticism than confidence was exhibited. He was at first himself disinclined to operate when there were no external symptoms of suppuration in the mastoid, or when in acute otitis media there was free discharge of healthy pus through the external meatus. At present, however, he had not only changed his opinion on these two points, but he considered the operation indicated in certain cases in which the membrana tympani is intact, and no suppuration or fluid is expected in the tympanic cavity and the mastoid cells. These are the cases of sclerosing or condensing mastoiditis. (Buck.) He distinguishes, therefore, the indications for opening the mastoid, each of which is illustrated by a case.

Case I. Acute tympano-mastoiditis; no relief by paracentesis of the membrana tympani and by free discharge. Rapid cure by opening the mastoid, and liberating a great quantity of pus.—In this case, an acute otitis media set in after taking cold, and persisted for several days, notwithstanding energetic treatment. On the eleventh day, the bulging membrana tympani was incised, and a liberal discharge of pus took place. Yet the pain continued, and settled gradually more in the left side of the head, up to the median line. Discharge from the ear unabated, but the post-aural region became swollen and tender on pressure. No ophthalmoscopic abnormality. About five weeks after the beginning of the disease, he opened the mastoid with a chisel. The outer layers of bone were healthy, but the bone became more vascular the deeper he penetrated. At last, when he had reached about one centimetre, he struck thick, creamy, inoffensive pus, which flowed off quite freely after the opening was enlarged. The wound was cleansed, and a silver tube inserted. Relief was immediate, and recovery rapid.

Dr. Knapp stated that in this case the suppuration was evidently more pronounced in the mastoid than in

the tympanum, and the swelling of the mucous membrane at the posterior wall of the tympanum prevented a free escape of the matter produced within the cells of the mastoid process. Such cases can get well, without operation, even when the symptoms may be graver than in the one just presented, as is evident from some well-known cases in literature. But the duration of these cases generally extends over many months, and in many cases recovery is not attained before a spontaneous opening occurs. In some cases, a lethal termination takes place, which might have been avoided by the operation. When, therefore, in spite of perforation or paracentesis of the membrana tympani, and more or less free discharge, the cerebral symptoms, and in particular constant headache, radiating from the mastoid over the side and back of the head, continued unabated for some time, he believed the operation to be indicated.

Case II. Chronic suppurative tympano-mastoiditis; no external abnormity; chronic half-sided headache; opening of mastoid, liberating puriform secretion; relief.—In this case, there was otorrhœa on the right side for twelve years. There also was a complaint of constant pains in the right side of the head, lasting all the forenoon, diminishing somewhat in the afternoon, and frequently most intense at night. Osseous portion of the external meatus narrowed by bulging of its posterior upper wall. Membrana tympani not recognizable in its details. Mastoid region healthy, and not tender to the touch. No discharge from the ear for three weeks, and during that time increase of the pain. With the reappearance of the discharge, the headache was slightly relieved. The granulations at the bottom of the canal were treated with alcohol, and considerable improvement was obtained. The bulging at the posterior upper wall of the canal appeared to be a mamillary exostosis. During the winter, there was an occasional return of the discharge, and the headache was very intense. Swelling in the posterior wall of the canal hard, and tender when touched with a probe. Notwithstanding the normal appearance of the mastoid, a diagnosis was made of chronic muco-purulent tympano-mastoiditis tending to sclerosing, and the operation was decided on. Two centimetres of nearly compact bone had to be gone through before a small cavity was reached, from which a few drops of secretion, more sero-mucous than purulent, escaped. During the progress of the operation, his diagnosis of sclerosing mastoiditis became verified, as the outer layers were very compact and pale, the deeper layers more and more hyperæmic. Relief from pain was almost immediate, and, although the wound is still open and treatment still continued, recovery is surely progressing.

In this case, only a small quantity of fluid was found; no cheesy masses, no granulation-tissue, no sequestra. Yet the perforation of the compact bone produced a freedom from pain which it was impossible to obtain by any other means. The experience of every one who has performed the operation many times shows these cases, in which one has penetrated deeply in the compact bone, so deeply, in fact, that one is obliged to desist without evacuation of any secretion, or even without penetrating any cavity at all, relief was afforded, and this was attributed to a so-called "revulsive" action of the operation, whatever that might be.

Case III.—In his third case, one of sclerosing mastoiditis, with intact membrana tympani, he performed the operation intentionally for this purpose. There were constant cerebral symptoms. The mastoid on the affected side was larger than on the other side, and the integument swollen and red, while the ear-canal was narrowed by a bulging of the walls. Mastoid process tender to the touch, especially at posterior margin. Membrana tympani white, opaque; handle and folds visible; cone of light absent. The operation was undertaken with the understanding that no purulent secretion should be found; at most, only sero-mucous or serous, but more probably no discharge at all; and so it proved during the operation. The mastoid cavity was reached, and explored with a probe. There was free bleeding, but no secretion. Capillary pulsation was very marked. The headache and dizziness were immediately relieved, and the patient made a rapid recovery.

Dr. Knapp further went on to describe his method of operation. When there is no place of peculiar swelling or softness, he chooses for his incision the little place known as Desmarres's pit, a little depression behind the upper level of the meatus. To keep the lips of the wound open, he uses Desmarres's rakes for the obliteration of the lachrymal sac. Of late years, he uses the chisel for the perforation. Two sizes of chisels were shown. They are smaller than commonly advised by authors. An oblong wound is made in the bone with the longest diameter in the vertical direction, and the direction of the force of the chisel is from above downwards, and from down upwards, rarely lateral. The direction of the wound-canal is parallel to that of the ear-canal, Removal of splinters is easily made by the chisel itself. For absorption, he uses fine sponges, and not absorbent cotton. If he wants the wound to heal by first intention, he applies sutures. In acute suppurative otitis, in which the evacuation of pus is sometimes sufficient to cause a speedy recovery, he simply covers the wound with absorbent cotton, waiting to be guided in the further treatment by the course of the disease. When there is old suppuration, or when profuse suppuration sets in a few days after the operation, he syringes the mastoid cavity, and inserts a perforated silver tube, and keeps this treatment up until the discharge has ceased.

DR. J. A. LIPPINCOTT, of Pittsburg, Pa., presented

A CASE OF MASTOIDITIS INTERNA CHRONICA WITH SCLEROSIS; TREPHINING; RECOVERY.

His patient was a young lady of nineteen, who in March, 1883, complained of pain in the right ear, not constant and of moderate severity, but which had lasted for several months. There was impacted cerumen, and after its removal the external canal and the membrana tympani exhibited rather more than the usual degree of redness and irritation, and the hearing was but slightly improved. Tubes not patent on either side. She appeared again in April, five weeks after the first visit, complaining of intense pain, referred partly to the region of the middle ear and partly to the mastoid, occasionally shooting over the whole side of the head. The mastoid region was swollen and sensitive, but not discolored. External meatus swollen, otherwise healthy looking. Membrana tympani free from congestion, but light cone absent. Moderate febrile disturbance. Leeches and poultices were advised with

the administration of the mild chloride internally, and aconite. Under this treatment the swelling rapidly subsided. After eleven days it returned, also swelling and sensitiveness in the mastoid region. And this continued for about a year after his first examination of the case, never showing any other cerebral symptoms but the pain, which was always now referred to the mastoid region alone. He then obtained the patient's consent to the operation, which was begun with the conical trephine, but on account of the extreme density of the osseous tissue, the trephine was soon abandoned for Buck's drill. The drilling was continued to a depth of 17 mm., and then he desisted, although no cavity had as yet been reached. The operation was entirely successful with regard to the removal of the pain, which greatly diminished immediately after the operation, gradually left her entirely, and the wound healed kindly. When Dr. Lippincott saw his patient, one week ago, she declared herself perfectly well.

Dr. A. H. Buck stated that when he received the call for the meeting he found that the subject of mastoid disease was well taken care of, and he, therefore, had abandoned his idea of writing a paper, but would confine himself to making a few remarks. He said he had noticed one point of practical interest. He drew the inference from some remarks in Dr. Knapp's paper that he tried to procure union by first instance. One of the beneficial effects of the operation was the subsequent irritation and drainage from that region, and he, therefore, prevents closing for a period of days. He keeps up a certain amount of surface irritation, which does the patient no harm, but acts as a counter-irritant.

Dr. C. J. Kipp, of Newark, N. J., stated that he sometimes met cases in which a necrosed spot showed in the bone, and he selected such a place for his operation. By advancing carefully he would often encounter a sinus, which led directly to the cavity.

Dr. S. Theobald, of Baltimore, spoke of the beneficial results which might follow in these cases if more stress were laid upon constitutional treatment, especially that with mercury.

Dr. S. Sexton, of New York, showed some illustrations of cases of mastoid diseases that recovered without operation. He believes that, if needed, nature always has provided a place for making an incision. In a very large number of cases he has met only one death from meningitis. His experience leads him to believe that the mastoid cells were generally invaded to a greater or less extent in every case of suppurative otitis media, and that we cannot rely upon pain in the mastoid as the only guide. He reported a case of death from abscess of the brain, where he did not think an operation on the mastoid would have helped. Not mastoid disease, but neuralgia causes the meningitis. There is generally found a place in the external auditory canal which points, and a free opening on that place gives exit to the pus and relief from the mastoid symptoms. In many cases of evident mastoid inflammation he has performed paracentesis of the membrana tympani, gave calcium sulphide internally, and advised outdoor exercise and nutritious diet, and his patient got well. Pain he relieved by quite small doses of aconite tinct. He has not felt satisfied with the indications for opening the mastoid as given at present, and would perforate if he had the certainty of finding pus, not otherwise. He asked what Dr. Knapp meant by capillary pulsation.

Dr. S. J. Jones, of Chicago, thought that if there is tenderness, redness, or swelling, the only doubt that could be raised was whether the inflammation were periosteal or deeper seated.

Dr. W. W. Seely, of Cincinnati, thought that Dr. Knapp misinterpreted the feeling of the Society in the discussion of last year. He only believed that it was difficult to formulate general terms when to operate: he could not find what indications might be of service to him, and he reported a case in which he thought operation was certainly indicated, and he prepared himself for it, but postponed, and gave the patient a dose of twenty grains of quinine, and he got well. He laid stress on the importance of local applications, especially great heat.

Dr. J. A. Andrews saw a boy who had been suffering from purulent middle ear disease for eighteen months. On his third visit found the boy restless, and made an ophthalmoscopic examination. Detected swelling of the disk, and upon this ground, with no indications in the external meatus and no redness over the mastoid, he perforated the bone, and found little pus and much broken-down tissue. A few weeks later he removed a sequestra.

Dr. Sexton asked what conditions of the mastoid cells would lead to optic neuritis.

Dr. Thos. R. Pooley reported a case in which the mastoid had been perforated, and in which no optic neuritis was found before the operation. It developed, however, after the operation.

Dr. Kipp had seen cases of death from mastoid disease, in which no optic neuritis was found. In answer to Dr. Sexton's question, he said we must assume that the optic neuritis is caused either by inflammation of the dura or of the cerebrum itself.

Dr. A. Mathewson, of Brooklyn, had not seen such decided results as to encourage him in taking so much risk. He has a specimen in which the lateral sinus was so deep that it must have been entered in operation.

Dr. B. E. Fryer called the attention of the members to the necessity and advantage of an early operation before the patient's constitution has run down, so as to prevent pyæmia, which is apt to follow operations on bone. He thought the optic neuritis a symptom of pyæmic poisoning.

Dr. Sexton believed that optic neuritis comes from meningitis, and this from mastoiditis, hence the operation, when undertaken on account of the appearance of optic neuritis, would anyhow be too late.

Dr. Kipp answered that cases get cured after operation.

Dr. Knapp said that by operation both the meningitis and mastoiditis may be cured. Whenever cerebral symptoms exist or increase he would operate. If the case improves and pain becomes less, he would let well enough alone. Optic neuritis certainly comes from meningitis, induced by mastoiditis, and the removal of this cause becomes a vital question.

Dr. A. Alt stated that even hyperæmia of the mininges may cause optic neuritis, and therefore operation will be beneficial by removing the cause.

Dr. A. H. Buck stated the following plan of proceeding: He divides cases of suspected mastoid dis-

ease into such as were formerly well, and those in which purulent discharge from the ears occurred. If there had been purulent trouble for years, sclerosis of the mastoid cells might be assumed to exist. There will not be redness or tenderness, nor swollen glands, yet there may be serious disease which demands operation. A second question is, whether the seat of purulent disease be provided with free exit. If so, operation would not be necessary. In acute cases he would freely operate, because he considers it good surgery, and his experience has given very favorable results; however, this point might be discussed. He questioned especially the condition of the tympanic cavity. If the outlet is adequate, we can try different things, and when they fail, open the mastoid. We will never be able to state whether we will find matter or simple congestion, but it always remains good surgery. If we do not find matter, the operation will do good by counter-irritation; if there is matter, then by its removal.

DR. KNAPP answered a question raised by Dr. Buck at the beginning of the discussion, with regard to procuring union by first intention, that he referred to cases of non-suppurative mastoiditis, when the cranium was entered. To Dr. Sexton's question about capillary pulsation, he says it is the same pulsation which is found in every inflamed part. The pulsation by which we may discover a small perforation in the drum-membrane is capillary pulsation, not from the carotid. He defines his indication for operation, constant pain radiating over the head, originating in or around the ear, more or less distress by overwork. Twice he operated for this symptom only. Besides there were the usual symptoms and histories of middle ear disease.

DR. A. H. BUCK, of New York, read a paper entitled

REMARKS ON THE USE OF LARGE DOSES OF IODIDE OF SODIUM OR IODIDE OF POTASSIUM IN CASES OF RAPID LOSS OF HEARING, SUPPOSED TO BE DUE TO SYPHILITIC DISEASE.

After referring to some cases reported by Roosa and Webster, and in which benefit had been derived from anti-syphilitic treatment, he described a number of cases treated by himself with large doses of iodide of potassium and of sodium. In the majority of these cases no improvement had followed, while in one or two there had been slight temporary benefit. He asked if the doses of iodide should be pushed to a still higher point (525 grains per day in one case), or should it be continued for a longer time.

DR. POOLEY had seen very few cases—only five or six—but found in his records only one case which apparently improved by treatment with iodide of potassium and iodide of mercury. There had been iritis three or four years ago. He made an unfavorable prognosis, but when he saw the patient again, six weeks later, his hearing had considerably improved. He referred to one case in which large doses of potass. hydriod. had induced intense coryza and acute angina and acute otitis with perforation, finally changing to a prolonged attack of otitis media purulenta.

DR. KNAPP mentioned three cases in which the result was completely negative.

DR. SEXTON had seen fifteen or twenty cases. The deafness in some of these cases, he thinks, resembles that of cerebro-spinal meningitis. He believes that the tolerance of the system to potass. hydriod. depends very much on the mode of administration. In cases in which benefit was derived, one would not be justified in attributing this to the very large doses; he believes smaller doses would have done the same.

DR. BUCK stated that if, after three weeks of moderate use no improvement follows, he believes it will be of no avail to push the doses much further.

DR. ANDREWS reported a case in which two drachm doses for three times a day had improved both sight and hearing. He has seen a number of sailors who were totally deaf, but never saw any improvement even with ounce doses of potass. hydriod.

DR. BUCK said that he is inclined to believe that the nature of the disease is a gummatous tumor. Such a tumor in another part of the brain may be absorbed, and the symptoms of pressure removed. In the labyrinth, however, pressure would destroy Corti's organ, and yet the gumma might undergo absorption, but the patient would remain deaf.

The Business Committee at this time proposed an adjournment till 8 P.M.

EVENING SESSION.

After reading of the records of the first session, the Secretary gave notice of a request, received from Prof. F. D. Clarke, of the New York Institution for Deaf-Mutes, a member of a committee appointed by the National Convention of Articulation Teachers, to confer with the Society with regard to the improvement of hearing in deaf-mutes where a certain amount of hearing still exists. Prof. Clarke was introduced to the Society, and requested to be present at the reading and discussion of the papers to be read.

DR. W. W. SEELY, of Cincinnati, read a paper on

THE JEQUIRITY TREATMENT OF SUPPURATIVE OTITIS MEDIA.

Considering the effect of jequirity on trachoma, he believes that although there are a large number of cases in which cleanliness, maintaining of patulency of the Eustachian tubes, and getting the nasopharynx in a healthy state are all sufficient, there are cases in which the mucous membrane of the tympanic cavity gets into a state that can practically only end by its becoming changed into cicatricial tissue, like the conjunctiva in trachoma, and that jequirity can be applied with benefit in such cases of middle-ear disease. He has used it both in hospital and private practice with a fair proportion of good results. The solution is simply put in the ear by means of probe and cotton, and a few drops further poured in. There always results profuse discharge, and sometimes a good deal of pain.

DR. THEOBALD inquired what was the strength of the solution.

DR. SEELY replied the same strength as is applied to the eye—a saturated solution.

DR. POOLEY said that Dr. Brandeis had reported one case in which very alarming symptoms occurred by producing inflammation of the throat, with which the medicine had come in contact.

DR. KNAPP thought that there might be less danger of the application to the ear than to the eye.

DR. SEELY said that the local reaction in his cases was very strong.

DR. J. J. B. VERMYNE, of New Bedford, read a paper on

DISEASE OF THE ETHMOID, THE CONSEQUENCE OF CHRONIC CATARRH OF THE NASOPHARYNX; EXOPHTHALMOS.

He stated that the case came under his treatment for the most prominent symptom, the protrusion of the eyeball, but since Dr. Knapp, in the April number of the present volume of the *Archives of Otology*, had reported a similar case, and diseases of the nasopharynx were a most important cause of ear-disease, and as such came under the treatment of otologists, he would report it before the Otological Society. In this case there was a tumor, the size of half a hazel-nut, stretching from the upper, inner corner of the eye, of bony hardness, slightly nodular, immovable, and intimately connected with the os planum. The right eye is slightly pushed forwards and outwards. There is no interference with the motion of the muscles or with the vision. Ophthalmoscope shows disk slightly raised and vessels distended.

There is a history of chronic nasopharyngeal catarrh during eleven years, and of an occasional temporary appearance of the eye as if it was pushed forwards. The case was believed to be either exostosis of the os planum or retention tumor of the ethmoid. Two cases reported by Dr. Knapp are referred to, in which removal was followed by recovery in one, by death in the second case. In view of the history of this second case, the writer believes that operation in such cases is not justifiable to the extent advocated by Dr. Knapp in his first case.

DR. KNAPP said that in these cases there mostly was polypus in the frontal sinus, even some degeneration.

DR. KIPP spoke of a case in which the nasal, ethmoid, and sphenoid cavity were all reduced to one cavity. He also made mention of a case in which the patient was relieved by pressure only. The discharge was pus. The pressure was applied by the fingers. He further used nitrate of silver spray on the Schneiderian membrane.

DR. J. J. B. VERMYNE also presented a paper on

MYXOFIBROMA AT THE BASIS CRANII, CAUSING BLINDNESS, AND, SEVEN YEARS AFTER, COMPLETE DEAFNESS BY DESTRUCTION OF THE LABYRINTH.

This case was first seen in January, 1876, when there was a complaint of fatigue of the eye and occasional dimness of vision; sight somewhat decreased; congested papillæ and retinal vessels, but no other complaints whatever. Three months later intense headache and optic neuritis led to the diagnosis of cerebral tumor. A slight improvement was obtained, but on the writer expressing an opinion with regard to the nature of the case and the unreliability of the relief obtained, the case passed out of his hands. It was seen again five years later, when there were secondary atrophy and entire loss of perception of light; and again, in 1883, when she had become suddenly deaf. Six weeks after, hearing returned, continued good for about six months, and then disappeared. Patient died May, 1884. Autopsy revealed a tumor 6 cm. long, 4 cm. wide, and 2 cm. thick in the left inferior occipital fossa, which had compressed the left cerebellum to one third its normal size. Brain and cerebellum both anæmic, the latter of increased consistency; much fluid in the ventricles. The most recent part of the growth had impinged upon the petrous part of the left temporal bone, causing entire destruction of the bone between the posterior wall and the tympanic cavity, which lies open. Membrana tympani entirely intact. The tumor was myxofibroma.

DR. C. J. KIPP, of Newark, N. J., read a paper on

TUMORS OF THE AURICLE.

He reported a case of epithelioma of the auricle in a healthy boy of nineteen, which appeared one week before the case came under observation. The concha was the seat of a small fleshy growth with granular surface. On the upper part of the auricle there were several boils, and below the ear was an enlarged gland. The hearing was not impaired. The diagnosis of granuloma was made and its removal advised. This was done, the whole growth being thoroughly removed with a sharp spoon. The wound healed completely in about a week. At this time a furuncle developed in the external canal and others appeared under the ear. Since then the patient has not been seen. Microscopic examination of the growth showed it to be made up largely of epithelial cylinders. The stroma was very vascular.

He also demonstrated a specimen of cavernous fibrolipoma removed from the upper part of the auricle of a man of thirty-five. The growth existed several years, but had grown much lately, only one month before he saw the case. The tumor was about the size of a hickory nut and was removed by excision. There was very little hemorrhage, and the wound healed kindly. Microscopically, the tumor was found to be lipoma, with considerable fibrous tissue between the lobules, and these had undergone cavernous metamorphosis. Growths of this kind are believed the only found in this locality. He also showed a large atheromatous tumor, which he had removed from the helix of the auricle.

DR. L. HOWE, of Buffalo, N. Y., then read a paper on

HÆMATOMA AURIS IN A SANE PERSON, TREATED WITH INJECTIONS OF ERGOT.

The patient, twenty-eight years old, was of excellent general physical condition. Mental development fair, but could not be called very intelligent, and six years ago had occasional attacks of dizziness. Four years ago a swelling occurred on the left ear, and continued to increase in size so rapidly that in a week or two it had attained its present size. Meatus closed by swelling and hearing greatly impaired, but no pain. About a month ago a similar tumefaction occurred on the other ear. The tumor on the left side filled almost the entire cavity of the concha; tragus and antitragus about double the thickness of those of the other ear. Skin slightly darker, and could be freely moved, and on firm pressure the tumor yielded perceptibly. The appearance of both ears was illustrated by plaster casts. It was treated by injection of two minims of the fluid extract of ergot. It produced considerable pain, and at first there was some tendency to sloughing. In about a week the injection was repeated, the dose increased to four minims, and subsequently alternately at intervals of eight or ten days for nearly two months. The tumor slowly decreased in size to nearly one-half its former size.

DR. SEXTON showed some photographic illustrations

of hæmatoma auris. He stated that it is not confined to the insane, but he has seen it very often in pugilists from so-called cross-counter on the left side. In the insane he thinks it is also due to trauma. He used to try injections of tinct. iodide, but it never did any good. In mild cases he aspirates; in case of large clot he uses an incision.

DR. POOLEY remarked that in the Epileptic Hospital in New York he had seen one case of double hæmatoma auris and detachment of the retina in both eyes, brought on by the patient.

DR. O. F. WADSWORTH, of Boston, present by invitation, said that, according to Virchow, the statues of Greek boxers have their ears deformed, as if suffering from hæmatomas.

DR. SEXTON further showed some cases of sarcoma of the concha, some cases of malformation, external fistula auris, malformation with unilateral atrophy of the face, nævus, malformation of the auricular cartilage, and torticollis consecutive to otitis media purulenta, all by photographic illustrations.

He also made some verbal remarks on the influence of dental irritation on the ear, and showed a new instrument for the removal of tonsils. Further, a few observations on the use of peroxide of hydrogen in ear diseases.

A paper was then read by DR. CHARLES A. TODD, of St. Louis, Mo., on

NECROSIS OF RIGHT LABYRINTH; TOTAL FACIAL PARALYSIS ON THE SAME SIDE; PARTIAL CURE.

The case was that of a female, aged nineteen. At four years had measles, followed by discharge from both ears, persisting up to the time of her appearance at the clinic, that is, for fourteen years. Under treatment improved, but afterwards neglected the case, which caused frequent relapses. Under the dry method the condition was greatly improved. In 1882, deep-seated mastoid pain, but no swelling or redness over the mastoid. This subsided under treatment, but there was manifest complete paralysis of the right side of the face. Dead bone was felt at the bottom of the meatus amidst abundant granulations. A first attempt to remove the sequestrum failed on account of its being still fixed; but a second attempt was successful, and then the granulations gradually disappeared. There was complete loss of taste in the territory of the chorda tympani. Later, a gradual improvement took place.

THE PRESIDENT, DR. CHARLES H. BURNETT, of Philadelphia, forwarded a paper on

REFLEX AURAL PHENOMENA FROM NASOPHARYNGEAL CATARRH; OBJECTIVE AND SUBJECTIVE NOISES.

(See page 88.)

PROF. F. D. CLARKE read a short paper, setting forth the opinion of educators in deaf-mute institutions that a large percentage of pupils in the schools are still possessed of a certain amount of hearing, and asking the Society if they believed this remnant of hearing might be increased by education, and requesting their coöperation in this matter. He also explained a new instrument, invented by Prof. Graham Bell, for testing the hearing power. The instrument itself was not yet ready for exhibition or experimentation.

DR. SEXTON did not believe it possible to increase the power of hearing.

The discussion was further participated in by DRS. JONES and LORING, who took rather opposite views with regard to the reliability of the causes of deaf-mutism, as given by the parents.

On motion of DR. HOWE, it was decided that the subject should receive official recognition by referring it to a committee of three, of which the President shall be one member, he to select the two other members.

Dr. Theobald exhibited some improvements in the nose-piece of Politzer's douche, and Dr. Andrews and Dr. Sexton improved instruments for applying powders to the ear.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. Charles H. Burnett, of Philadelphia.

Vice-President.—Dr. J. S. Prout, of Brooklyn.

Secretary-Treasurer.—Dr. J. J. B. Vermyne, of New Bedford.

Committee on Publication.—Drs. J. J. B. Vermyne, C. J. Blake, and J. O. Green.

Committee on Membership.—Drs. J. Green, H. G. Miller, and H. D. Noyes.

It was voted that the Society should meet next year at the same place as, and on the day preceding the meeting of the American Ophthalmological Society.

Adjourned.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twentieth Annual Meeting, held at Grand Hotel, Catskill Mountains, July 16 and 17, 1884.

(Specially reported for THE MEDICAL NEWS.)

WEDNESDAY, JULY 16TH—FIRST DAY.

MORNING SESSION.

THE Society was called to order by the VICE-PRESIDENT, DR. WM. F. NORRIS, of Philadelphia.

The Treasurer's Report was received and referred to an Auditing Committee.

DR. RICHARD H. DERBY tendered his resignation as Secretary, which was accepted, and Dr. O. F. Wadsworth, of Boston, was elected to fill the vacancy.

Drs. Sutphin, of Newark; Parrot, of Brooklyn, and Andrews, of Philadelphia, were invited to take part in the deliberations of the Society.

DR. HASKET DERBY, of Boston, read a paper on

IRIDECTOMY IN CHRONIC IRITIS.

After briefly considering the literature of the subject, the question was asked, Does iridectomy cure or ward off the disease? Instances of the performance of the operation under such circumstances are so rare that the report of a single case has its value:

Miss D., aged sixty, was seen November 13, 1880, complaining of "cold" in the left eye; this had lasted three weeks. It was characterized mainly by redness and dimness of vision; there was little pain. There was much ciliary injection, and numerous posterior synechiæ were found. Under atropine, a shade and rest, the synechiæ were broken up, and in five days the eye was as well as ever. November 18th, a similar attack appeared in the other eye; this disappeared under similar treatment. On the 29th, the first eye was again attacked. A course of salicylic acid was now

commenced. December 8th, there was a slight relapse in the right eye, and a severe attack immediately afterwards. Iodide of potassium was then administered. On the 11th, there was much improvement. Ophthalmoscopic examination showed both fundi to be normal. Iron was given in alternation with the iodide. Between January 1 and June 3, 1881, there were nineteen attacks in the right eye and fourteen in the left. Various plans of treatment were employed, but with no benefit. June 23, 1881, atropine was begun and applied daily until July 6th. There were no attacks during this time. On its suspension, a severe attack appeared in the right eye. The atropine was then ordered three times a week for two months. Under this treatment there were no attacks. When this was discontinued an attack occurred. Subsequently she went to Europe and consulted a physician, who diagnosticated glaucoma, and performed iridectomy on both eyes.

Gradually the attacks ceased, although slight redness occasionally occurred. It was considered, however, that the improvement was not due to the operation, but was dependent on the fact that the malady had worn itself out. He did not think that iridectomy would be justified in another similar case.

DR. H. KNAPP referred to the fact that in many instances recurrent iritis ceases spontaneously after continuing for many years. He restricts the operation of iridectomy to those cases in which, besides iritis, there is a tendency to cyclitis and glaucoma. Where the condition is one of genuine iritis with limited adhesions, and a part of the pupil moves freely, he does not perform iridectomy.

DR. CHARLES S. BULL, of New York, presented a paper entitled

CASES OF RESTORATION OF THE EYELID, BY TRANSPLANTATION OF FLAP WITHOUT A PEDICLE, BY WOLFE'S METHOD.

He described three cases, in two of which the upper lid, and in the third the lower lid, was greatly everted. In all the method of operation was similar, and consisted in first loosening the adhesions and freshening the surface of the affected lid. A flap was then taken from another part of the body, in two instances from the forearm, and in the third from the chest, and, after being carefully freed from fat and subcutaneous tissue, was applied to the denuded surface, and, if necessary, confined in position with sutures. The part was then covered with gold-beaters' skin, over which several layers of iodoform gauze were placed, and the whole confined in position with a compress of borated cotton and a roller bandage. The dressings were not removed for three or four days, after which time the wound was dressed every day or every other day. In the third case, in which the lower lid was operated on, the epidermal layer of the flap sloughed, but the result was very satisfactory. In the other two cases no trouble was experienced, and great improvement was effected.

The next paper read was by B. E. FRYER, M.D., U. S. Army, and was entitled

A SUCCESSFUL CASE OF SKIN TRANSPLANTATION WITHOUT PEDICLE TO THE LOWER LID AFTER REMOVAL OF AN EPITHELIOMA.

Successful cases of transplantation of skin flaps from distant parts without pedicle have perhaps been sufficiently numerous to give the operation a permanent place both in ophthalmic and general surgery. Later operators have not followed the plan of Wolfe, the originator of the procedure, but have sought more especially for a simpler dressing than he employed.

The following case is reported: Mrs. E. P., aged forty-one, not of strong constitution and not in good health, had suffered from epithelioma of the left lower eyelid and a part of the adjoining cheek. The growth extended from one-fourth of an inch from the inner canthus to a short distance beyond the external angle. It involved the tissue of the lid to within 2½ mm. of the cilia and in one portion included the site of the cilia. Its breadth was about half an inch. The disease had lasted one year when the case came under observation (March 20, 1884). The growth was steadily extending. On March 27 the epithelioma was removed by excision. A few small arteries were twisted, and the eyelids then were brought together by two fine silk sutures. This left a crescent-shaped wound one and a quarter inches long and three-quarters of an inch at its greatest breadth. Laying out a flap on the left forearm, nearly twice the size of the wound, but leaving one portion uncut, the flap was turned on itself and all the subcutaneous tissue and fat removed with scissors. The uncut portion was next divided and the graft placed on the wound and moulded into position with gentle pressure. A layer of gold-beater's skin plaster was applied and pressed into the hollows and irregularities of surface, pressure being made with a compress of absorbent cotton which had been dipped into water at a temperature of 100°. The plaster extended an inch above and below the eye and half an inch laterally. A second layer of plaster was then applied. It was then found that the plaster held the flap in position and the edges in apposition with those of the wound, which is a point of great importance. As the plaster became dry it made a firm dressing, holding the parts in a splint, as it were. As the patient was exposed to cold shortly after the operation, a dressing of absorbent cotton was applied over the plaster, but this was removed when the patient reached her home. On the seventh day after the operation, a portion of the plaster and the stitches holding the lids together were removed, and perfect union found. On the eighth day all the plaster was removed. At the present time, three months after the operation, the graft closely resembles the surrounding skin, and there has been but slight contraction.

DR. RICHARD H. DERBY, of New York, described a case of

GANGRENE OF THE LID, WITH SUBSEQUENT RESTORATION OF TISSUE, WITHOUT PLASTIC OPERATION.

Two weeks before coming under observation, in November, 1883, the patient noticed beneath the lower lid a small black discoloration. The following morning, the whole side of the face was swollen and the eye closed. When seen, there was a sharply defined black surface, corresponding to the anterior margin of the orbit, in a condition of slough. There was a clear line of demarcation. The patient was lost sight of for four weeks. He returned with a deep cicatrix at the margin of the orbit, the skin having restored itself. The eyebrow was drawn down one-quarter of an inch. There

was incomplete eversion of the lower lid, but the eyeball was intact. The patient had incomplete control of the upper lid.

These papers were discussed by Drs. Pooley, Prout, Harlan, Little, Howe, Andrews, Lippincott, Fryer, Green, and Wadsworth.

DR. GEORGE C. HARLAN, of Philadelphia, described a case of

HYSTERICAL MONOCULAR BLINDNESS, WITH MYDRIASIS AND BLEPHAROSPASM.

It was found that the patient was always relieved by the application of a Charcot magnet. The attempt was then made with a piece of wood shaped to imitate the real magnet. The experiment was entirely successful, the imitation acting even more powerfully than the real magnet.

DR. H. KNAPP, of New York, read a paper

ON NEURO-RETINITIS, WITH FULMINANT BLINDNESS.

Two cases were reported. The first was that of a gentleman aged forty, strong, healthy, and temperate, and without any constitutional disorder. On May 5, 1883, he had intense headache and nausea. In the evening, the sight became dim. He slept well during the night, but on awakening the next morning found that he was totally blind in both eyes. Dr. Knapp saw him, in consultation, the same afternoon. The general condition was excellent, and the patient was free from pain. There was no abnormity, with the exception of suppression of urine. Half an ounce was removed with the catheter. The pupil was widely dilated, and irresponsive to light. There was no perception of light. The mobility was normal. The media were clear, but in both eyes there were well-marked choked disks. The retinal veins were large and tortuous; the arteries small, and did not pulsate under pressure. There was no hemorrhage, and no white spots in the fundus. The attack was attributed to uræmia, although the examination of the urine gave negative results. He was ordered salicylate of soda, in sixty-centigramme capsules, every quarter of an hour, until profuse perspiration should occur, and this was to be kept up by the use of hot drinks for two hours. The condition continued about the same. On the fifth day, the arteries appeared to be a little fuller, but did not pulsate on pressure. Iodide of potassium and calomel were then ordered. Shortly afterwards, hypodermatic injections of strychnia and electricity were added. The case was seen in consultation by a number of prominent physicians, and it was agreed that the most probable explanation was uræmia. During the next two weeks, the amount of urine increased, and the disks became paler. Later, there were some pain and tingling in the left hand and leg.

Fifty-five days after the occurrence of the blindness, the patient said that he could see a little, but this could not be verified. Iodide of potassium in large doses was ordered. A recent examination showed that the patient could see objects held in a certain position. These could be best seen when held some distance from the eye. He could read Snellen 50 at a distance of two feet, and could correctly indicate playing-cards when held in the proper position. He could, however, not indicate the position of the window, but when turned towards the light could tell whether or not the eye was shaded. Dr. Knapp thought that the probable explanation of this case was some cerebro-spinal lesion, or some abnormality around the frontal lobes near the chiasm. There had been no other symptoms of Bright's disease.

The second case was that of a girl aged eleven and a half years, who was seen April, 1884. Two days previously there had been spells of loss of vision. At three P. M., she had blindness in the left eye. She slept well that night, but the next morning was totally blind in the left eye. In the right eye she could only see objects in the lower half of the visual field. By noon the right eye had also become blind. The following day both pupils were immovable, and both disks were swollen, the arteries small, the veins large but readily emptied by external pressure, which caused the arteries to pulsate. The urine was examined and found to be normal. The child was sent to a hospital, and profuse perspiration induced by salicylate of sodium, and calomel was given. The next day the condition was unchanged, but there had been profuse diarrhœa—twenty-four stools in twenty-four hours. The calomel was discontinued. On April 3d there was slight perception of light. From this time improvement was continuous, until in June she was completely well with normal vision. Dr. Knapp thought that there might have been something in the neighborhood of the chiasm or in the cavernous sinus with produced pressure on the optic nerve and caused neuro-retinitis. In this connection a case of exophthalmos from a communication with the cavernous sinus was referred to. The patient had been blind for three months, but as soon as she recovered from the effect of the ether after the carotid had been ligated, she was able to see.

Dr. Knapp thought that in the second case the treatment had something to do with the good result. If there had been serous exudation in the neighborhood of the chiasm, the induction of profuse diarrhœa and diaphoresis would be the best way to remove it.

DR. CHARLES KIPP had been taught to attribute optic neuritis to a cerebral lesion, but he had seen cases in which atrophy followed this affection, and in which the patient lived for a number of years. In one case which had been under observation for fifteen years there had been choked disk, but no other trouble could be discovered. He thought that possibly in some cases there was some other cause for the condition.

DR. KNAPP stated that there might be serious disease of the frontal lobes of the brain for a long time and yet no marked symptoms be presented.

DR. GEORGE C. HARLAN, of Philadelphia, had examined a large number of prtients in blind asylums who exhibited atrophy of the optic nerve, but yet were in excellent health.

DR. A. ALT, of St. Louis, described a case of neuro-retinitis with large hemorrhages, which was thought to be due to the presence of a cerebral tumor. At one time the condition was such that a fatal issue was looked for, but under the use of large doses of iodide of potassium, improvement began and the patient (a girl of eleven years) is now in perfect health. There is atrophy of both optic nerves.

The discussion was continued by Drs. Pooley, Wadsworth, and Andrews.

Dr. W. F. Norris, of Philadelphia, read a paper

ON HEREDITARY ATROPHY OF THE OPTIC NERVES.

He gave the history of a family of twenty-three persons, thirteen males and nine females, in which fourteen, nine males and five females, suffered from congenital atrophy of the optic nerve. The age of the individuals affected, ranged from seven to twenty-three years. In all, save one, the symptoms came on gradually. In the exception it is said to have come on in the course of four days. All the cases showed central scotomata. The treatment consisted of the use of bichloride of murcury and strychnia. In only one case did the treatment seem to have any influence on the disease. In this instance vision improved from $\frac{6}{60}$ths to $\frac{6}{24}$ths.

Dr. Norris also described

TWO CASES OF ORBITAL TUMOR,

which he reported on account of their rarity. One was a myxo-sarcoma of the orbit occurring in a child four months old, which was twice removed and at the second removal the actual cautery was applied, but after both operations the growth reappeared.

The second case was one of osteoma of the orbit in a widow thirty-two years of age. In this case it became necessary to remove the eyeball, and the growth which involved the lower portion of the of the orbit was chiselled away. Sight had been lost some time previously. There has been no return of the disease, and the woman is able to wear an artificial eye with comfort.

Dr. J. A. Andrews read a paper on

JEQUIRITY.

He attributed the disastrous results which had followed the employment of this drug in diseases of the eye to the use of too strong infusions. His plan is to begin with a one per cent. infusion, make one application, and then examine the case after twenty-four hours. The application is then repeated as often as necessary to secure the desired effect. If the drug is used in this way there is no little risk of doing injury. The infusion should be a fresh one.

Dr. S. Theobald, of Baltimore, referred to the great difference in the susceptibility of different individuals to this drug.

Dr. W. F. Norris had found that after repeated application the conjunctiva seemed to lose its sensibility to the action of jequirity.

Dr. H. S. Schell, of Philadelphia, stated that he had used preparations that had been made for a number of weeks with success. These had been preserved by the addition of four grains of boracic acid to the ounce.

Dr. O. F. Wadsworth, of Boston, had preserved the infusion active and free from bacilli by the addition of two per cent. of carbolic acid.

Dr. J. S. Prout, of Brooklyn, had never used jequirity, but he called attention to the fact that some years ago, he had presented to the Society a paper describing the good effects of the application of quinine for the conditions in which jequirity has been found of service.

AFTERNOON SESSION.

Dr. A. Alt, of St. Louis, demonstrated a number of *Microscopical Specimens*, and a *New Form of Perimeter*, designed by Dr. E. Dyer, was described by Dr. H. G. Miller.

EVENING SESSION.

Dr. H. S. Schell read a paper on

A CASE OF EMBOLISM OF THE CENTRAL ARTERY OF THE RETINA.

A woman seventy-one years of age, on January 2, 1884, suddenly lost vision in the left eye. This was preceded by a flashing of colors. Examination of the heart showed insufficiency of the mitral valve with hypertrophy of the left ventricle. The ophthalmoscope showed swollen disk and œdema of the central portion of the retina, but no red spot in the macula. In the inferior branch of the artery was a space involving the whole calibre of the artery, which appeared to be empty. After massage, by pressing on the ball, had been practised for some minutes, a current was induced in the vessels, but the blood stream appeared to be broken into sections. The case was treated with iodide of potassium, and after a time chloride of ammonium was substituted for the iodide. The patient was seen a number of times afterwards, and at the last observation the disk had become white and the arteries thread-like.

Dr. A. Mathewson described

A CASE ILLUSTRATING THE NATURAL HISTORY OF CATARACT.

A naval surgeon was operated on in 1863, and a cataract removed from the left eye, the operation being successful. The left eye was at the same time the seat of a senile cataract. He had been frequently treated during the past twenty years for attacks of iritis, which yielded to atropine. Two years ago he began to see better with the right eye, and on examination it was found that the cataract had disappeared. The lens was found in the anterior portion of the vitreous chamber, just below the ciliary region, and appeared to be fixed in that position. Two years later, he began to have occasional attacks of iritis, which subsided under the use of atropine. Last fall he had an attack which was not relieved by the atropine. He consulted Dr. Mathewson, who found the eye exhibiting the ordinary appearances of glaucoma. In the lower part of the anterior chamber was a large mass, looking as though a portion of the lens had broken off. A two grain solution of eserine reduced the tension, contracted the pupil, and cleared up the sight. There was no return of the pain for some weeks. The eserine gave only partial success, and the suffering was so great that on one occasion a hypodermatic injection of morphia was resorted to. This at once relieved the pain and the glaucomatous symptoms. After some days the condition returned, and morphia soon failed to give relief. The eye was then enucleated. The lens, on examination, was found to be extremely attenuated, hardly 3 mm. in diameter, and as thin as a wafer.

Dr. John Green, of St. Louis, described three similar cases.

DR. SEELY, of Cincinnati, gave his

EXPERIENCE WITH CERTAIN REFRACTIVE CASES,

alluding in particular to the results of lack of balance of the ocular muscles, and its relation to changes in refraction; the consideration of small amounts of *myopic astigmatism*, with or without blepharitis, with or without asthenopic symptoms; and the state called *mixed astigmatism*. He spoke of the necessity of always calling in question a small amount of myopia, especially of myopic astigmatism, and proceed to determine whether it really exists by paralyzing the muscle of accommodation. Illustrative cases were narrated.

As regards *mixed astigmatism*, he was inclined to think this state is not so frequent as one would be inclined to think; *i. e.*, if all cases of *mixed astigmatism* were thoroughly treated with paralysis of the accommodation, a very large number would be changed into simple *hypermetropic astigmatism;* in a word, the myopic part would be done away with. As regards *the influence of lack of muscle balance on refraction*, he cited, illustrative cases of apparent causative relation existing between insufficiency of the internal recti muscles and spasmodic myopia, which were treated by paralysis and prisms.

In conclusion, he said that his results, since insisting upon, first, a complete knowledge of the refractive state, and, second, of putting the eyes totally at rest for a few days by paralysis, had been infinitely more satisfactory than in former years.

He seemed to think there was some tendency to underrate refractive cases in general, and to practise on too meagre actual knowledge of the refraction, and insisted upon the necessity of paralysis of accommodation in a large proportion of cases, in order to get practical results.

The paper was discussed by Drs. Little, Mittendorf, and Theobald.

A paper entitled

THE CLINICAL HISTORY OF A CASE OF SYMPATHETIC OPHTHALMIA,

by DR. L. WEBSTER FOX, was read by the Secretary.

W. R., received a punctured wound in the inner lower quadrant of the left eyeball, the wound being situated near the cornea. Cold water and a bandage were applied. There was but little inflammation and only slight pain. The boy was allowed to use his eye, until some time later, dimness of vision of the right eye was observed. An ophthalmic surgeon was then consulted, and at once instituted vigorous treatment. The patient was at this time seen by Dr. Fox. There was haziness of the left cornea, the pupil was occluded, and there was perception of light. The iris of the right eye was much thickened and newly formed vessels could be discovered upon it. There was barely qualitative perception of light. There was no pain, but light could not be borne. Treatment with mercurials was begun and under their use the redness and other symptoms of inflammation disappeared, but there was no return of vision. The right eye is atrophied to half its former size, and there is no perception to light. The left eye is becoming atrophic and perception to light is doubtful.

DR. J. A. LIPPINCOTT, of Pittsburg, Pa., read a paper on

TWO CASES OF ORBITAL ABSCESS.

The cases were reported, first, on account of the rare occurrence of retro-ocular abscess; and secondly, because in one case there was complete recovery, and in the other case because of the early age at which the disease developed.

Case I.—In September, 1877, I. D., a rather feeble child, while recovering from erysipelas of the face and scalp, was noticed to have a slight swelling of the right upper eyelid. When the patient was seen, the day following, a small abscess of the lid was found. This was opened, but only a few drops of pus escaped. There was at that time no displacement of the eyeball, nor any loss of mobility, but there were more pain and tenderness than could be accounted for by the abscess in the lid. The patient was feeble, irritable, and emaciated; the pulse was weak and rapid; there were decided anorexia, great thirst, and high temperature. He was taking tonic doses of quinine and iron. After the abscess was opened, a poultice was applied, and the tonic treatment continued; the superficial abscess healed rapidly, but the pain and tenderness seemed slowly to increase, although no marked symptoms of inflammation manifested themselves. The patient was put on the syr. ferri iodidi in fifteen drop doses, every three hours, and the dose of quinine increased to six grains daily.

On the fifth day after the patient was first seen, the eyeball protruded slightly, although the mobility was perfect. Twenty-four hours later, a sudden and rapid increase of the exophthalmos took place, and was accompanied by a marked increase of the symptoms and of the fever. The eyelids were swollen and discolored, and there was almost complete ptosis. The eyeball protruded more than half an inch, was scarcely movable, and its axis was directed strongly downwards and outwards. The cornea was slightly exposed, but its transparency was not affected. There was slight chemosis of the conjunctiva. The pupil was small and feebly responsive. A satisfactory view of the fundus was not attainable, but it was determined that no gross lesion was present. The sight appeared to be unimpaired and diplopia was observed. There were considerable tension and severe pain. Tenderness was especially marked in the upper inner orbital region. With the aid of Dr. McCann, an exploratory incision was made above and a little to the inner side of the globe, and under the upper lid. No pus was found and a second incision was made a little further to the inner side. This revealed the presence of pus. The puncture was converted into a free incision, and about a drachm and a half of thick, foully smelling pus escaped. A great decrease of the tension followed, and there was a slight recession of the globe. After discussion it was decided to dispense with the use of a tent, and a large poultice was applied in such a manner as to produce some pressure. The following day the swelling of the upper lid was greatly intensified, and the conjunctival chemosis increased, but under a supporting treatment and the application of poultices and pressure the swelling subsided and the ball receded. Five weeks after the operation mobility of the globe had fully returned,

and the diplopia had completely disappeared. The exophthalmos persisted, gradually diminishing until about one year ago. Two days after operating on the right eye, it became necessary to evacuate an abscess which had formed beneath the left eye. No further treatment was required. A recent examination showed no trace of the disease, except a scarcely perceptible degree of protrusion of the right eye, the fundus being normal and vision $\frac{20}{xx}$.

Case II.—A. R., scarcely twelve months old, was seen September 14, 1880. Three weeks previously great swelling of the eyelids and chemosis occurred. There was no protrusion of the eye and no purulent discharge. The condition continued about the same for two weeks, when the eyelids became greatly swollen and the ball protruded to fully the extent of its diameter. Pupil widely dilated. This was the condition when seen by Dr. Lippincott. The pain was apparently not very severe. The temperature was 99°. An aspirating needle was introduced under the upper lid, and an abscess containing dark-brown, fetid pus was discovered. This was evacuated by a free incision. A poultice was applied, and quinine and iron prescribed. The day following, the lids were much swollen, but the general condition was improved. A week later it was found necessary to make a second opening, as the first had closed. The pus which now escaped was thick, creamy, and not fetid. A carbolized oil tent was inserted. Two weeks later the opening closed. The poultice was then substituted by a cold compress bandage. Symptoms of irritation appearing, poultices were again applied and continued two weeks. The eye continued to improve, and six weeks later there was only slight protrusion and mobility seemed perfect. It was impossible to determine the vision. The present condition is as follows: exophthalmos about one-sixteenth of an inch, considerable swelling of the lids and partial ptosis. Between the lower lid and the globe is a freely movable, pale, gelatinous-looking, lobulated mass, nearly three-fourths of an inch long and one-fourth of an inch wide. There is occasionally some discharge. The eyeball is perfectly clear and healthy in appearance. Mobility perfect. Pupil normal in size and responsive. Vision limited to light-perception. Media transparent. Disk presents decided white atrophy. Retinal vessels, especially the arteries, much contracted.

DR. CHARLES J. KIPP, of Newark, reported a

CASE OF ABSCESS OF THE FRONTAL SINUS, ETHMOIDAL CELLS, AND SPHENOID SINUS.

J. B., fifty-four years of age, was seen in March, 1883, complaining of double vision and pain in the head. For many years he had suffered with frontal headache; otherwise his health had been good. A year ago the diplopia was first noticed; the left eye was pushed downwards, outwards, and slightly forwards. The mobility of the eye was impaired. A nodular tumor was found involving nearly all the upper margin of the orbit. This protruded into the orbit as far as the finger could reach. The tumor was hard, and no fluctuation could be detected. The sight was normal, and the ophthalmoscope revealed only slight turgescence of the retinal veins. The case was considered one of sarcoma with periostitis of the orbit. A few days later an incision was made and the tumor found to consist partly of bone, but in the course of the examination the wall of the tumor gave way and a quantity of fetid pus escaped. The abscess extended upwards and backwards. The pus was evacuated and a drainage-tube introduced. When the patient recovered from the ether he complained of an odor in his nose and expectorated much fetid pus. The abscess was washed out daily, but on the eleventh day after the operation the patient was seized with pneumonia, which ended fatally six days later. At the autopsy it was found that the frontal sinus, the ethmoidal cells, and the sphenoidal sinus were converted into one large cavity containing pus, and numerous spicules of bone protruded from the walls.

The object in bringing the case before the Society was to learn whether or not there are any signs to enable a differential diagnosis to be made between tumors of the periosteum of the orbit and disease like that found in this case.

Dr. Kipp also reported another case of distention of the frontal sinus. Mrs. W., aged fifty-seven, consulted him in October, 1881, on account of a painful swelling below the left eyebrow, which had begun to appear six months before. She had suffered pain in this region for many years. There had been no injury, but nasopharyngeal catarrh had existed for a long time. The tumor was the size of a hickory-nut. It extended into the orbit as far as the finger could reach. It was hard, but on pressure fluctuation could be discovered. The mobility of the globe was slightly interfered with. In the nose there were simply great swelling and congestion of the mucous membrane. The case was considered one of distention of the frontal sinus, and an operation advised. This was declined. The patient was again seen in July of the following year. The tumor was somewhat larger; within a few days the eye had become red and painful, and a shallow ulcer of the cornea was present. The eye was treated with fomentations, boracic acid, and atropia. This caused the ulcer to heal. While examining the tumor it gave way, and the cyst was entirely evacuated, and a quantity of fetid, muco-purulent matter escaped into the mouth. Solution of nitrate of silver was applied to the nasal cavity, which was frequently washed out, and the cyst was evacuated by pressure several times a day. For some weeks the cyst would refill very quickly after being emptied, but by May, 1883, the pain had entirely disappeared and the cyst rarely became distended. The discharge has not been offensive for some months. The defect in the temporal bone is as large as a ten-cent piece, and the end of the finger can almost be pressed into the frontal sinus through it. Air not infrequently enters the frontal sinus when the nose is blown.

DR. LUCIEN HOWE, of Buffalo, read a paper on

THE CHANGES IN THE EYE IMMEDIATELY AFTER DEATH.

The examination was made on a man aged fifty-four, who died from phthisis. One of the conditions observed was wrinkling of the cornea, as seen under oblique illumination, and it was stated that this might readily be mistaken for rupture of the lens, a lesion which has been described as occurring in beheaded criminals.

THURSDAY, JULY 17—SECOND DAY.

DR. W. S. LITTLE read a paper on

A CASE OF DOUBLE GLIOMA OF THE RETINA, PROBABLY CONGENITAL.

The case was that of a child first seen in June, 1882, at which time double glioma was diagnosticated. Surgical treatment was refused, and mercury and iodide of potassium administered. The case went from bad to worse, and finally died in March, 1884. Photographs exhibiting the appearance of the child's head and eyes were presented.

DR. THEOBALD described a case in which four years ago he had enucleated the eye, and in which there had been no return. This patient is about twelve years old. A second case was related in which enucleation had been performed. There was no return of the disease, but one year later the child died from some affection of the brain, the nature of which could not be ascertained. This patient was about nine years of age.

DR. MITTENDORF asked if any of the members had seen a case in which the patient had not invariably died after operation for glioma.

DR. MATHEWSON thought that some of the reported cures could be explained on the ground of mistaken diagnosis.

DR. KNAPP said that there were well-authenticated cases of cure of glioma. The recoveries, however, are rare. He had had but one cure in his experience, and that case had been under observation for fourteen years.

DR. WILLIAM THOMSON, of Philadelphia, presented a paper entitled *A Partial Report of the Progress of the Examination of the Employés of the Pennsylvania Railroad as to their Color-sense and their Acuteness of Vision and of Hearing*, and also described the measures which had been taken to secure legislation on this subject.

DR. GEORGE C. HARLAN, of Philadelphia, reported

TWO CASES OF SWELLING OF THE OPTIC NERVE; POSSIBLY CONGENITAL.

In these cases, the swelling of the disk was discovered accidentally while the eyes were being examined for another purpose. In neither of the cases were there symptoms referable to the condition, and in neither did the swelling of the disk produce any trouble as long as the cases were under observation.

Similar cases were reported by DRS. RISLEY and MITTENDORF.

DR. GUSTAVUS HAY, of Boston, described two cases in which Bählman's hyperbolic glasses improved vision. In the first case, the cornea was unduly prominent, and in the second case there was distinct conical cornea.

DR. O. F. WADSWORTH, of Boston, read a paper entitled

A CASE OF MYXŒDEMA, WITH ATROPHY OF THE OPTIC NERVES.

The patient was a woman aged forty-two. There was no history of syphilis. Menstruation had always been regular until three years ago, when it ceased. The general health had been good. The first symptom of the disease was noticed six years ago. The lower part of the face and the hands and feet became swollen and œdematous, but did not pit on pressure. On one leg, varicose veins were found; but there is not much enlargement of either leg. The skin is not particularly dry, but she never sweats. The tongue is enlarged, and speech slow. The trouble with vision was first noticed eighteen months ago, and began in the right eye. When first seen by Dr. Wadsworth, a few weeks ago, there was simply light-perception in the right eye. In the left, $V = \frac{20}{XL}$, and the field was contracted upward and outward. No cause could be assigned for the occurrence of the myxœdema. The fact that atrophy exists is not a positive proof that the myxœdema and atrophy had any connection with each other. He had examined the eyes in other cases of myxœdema without finding any lesions.

DR. LITTLE had examined seven or eight cases of myxœdema, but had found no eye symptoms.

DR. T. R. POOLEY, of New York, read a paper on

ACUTE DACRYO-ADENITIS.

A girl twenty years of age had been suffering from trachoma and trichiasis. This was followed by diphtheritic inflammation of the conjunctiva of the left eye, which caused the destruction of the eye. Three weeks later a swelling at the outer upper angle of the right orbit appeared, which was exquisitely sensitive. Hot applications were ordered, and quinine and iron given internally. The following day an incision was made through the upper lid, but no pus was obtained. From this time improvement set in and continued, and when last seen she was perfectly well.

DR. KNAPP did not consider it a very rare occurrence to have inflammation of one lachrymal gland. The prognosis is invariably favorable. In none of the cases which he had seen had there been any conjunctival trouble or any infectious disease,

DR. W. F. MITTENDORF, of New York, read a paper on

POLYCORIA,

describing two cases of multiple pupil. In the first case there were five openings in the iris of the left eye, and in the second (the father of the first), there were two pupils in the right eye, the lower one being divided into two by a band passing across it.

DR. W. T. SEELY had seen a number of cases of polycoria in the members of a certain family, and in all the cases which he had seen the individuals had gone blind.

DR. MITTENDORF stated that the daughter was aged thirty-two and the father sixty-five, and that neither had exhibited any indications of blindness.

DR. SEELY, in reply to a question by the President, stated that they had gone blind with choroiditis.

DR. E. HUTCHINSON, of Utica, described the case of a man injured by a premature explosion of powder in such a way that the sight of the left eye was destroyed, and on the right side the contraction, which formed the cicatrix caused by the burning, prevented the opening of the eyelids, although the eye was intact.

The operation consisted of cutting deeply through the external commissure, dividing the ligament and dissecting it up. A web of conjunctiva was then planted into this opening. After he had recovered from this operation, a V-shaped piece was removed from beneath the

lower lid and the parts brought together. A very satisfactory result was obtained.

DR. JOSEPH AUB, of Cincinnati, read a paper on the

REMOVAL OF FOREIGN BODIES FROM THE VITREOUS.

He reported three cases in which by the use of an electric magnet he had been able to remove pieces of iron from the vitreous, and save the eye. In a fourth case the iron had become encapsulated, and could not be detached. Sympathetic ophthalmia appearing, it became necessary to enucleate the eye.

DR. KNAPP considered it not a difficult matter to remove the foreign body when it could be seen. Cases had been reported in which a foreign body which could not be seen was removed. He had himself reported one such case.

DR. MITTENDORF described a case in which a piece of iron had passed entirely through the eyeball, and was found lying behind the sclerotic coat.

DR. KNAPP stated that the opinion which he had formed from his own experience and from a study of the literature of the subject, was that it would be better at once to remove the eye into which a foreign body had entered, provided the body could not be seen. In this he thought that the greatest good to the greatest number would be given.

DR. MITTENDORF endorsed these views.

The discussion was further continued by Drs. Pooley, Hutchinson, Harlan, and Little.

DR. S. D. RISLEY, of Philadelphia, read a paper on

A CASE OF HYPERMETROPIC ASTIGMATISM PASSING INTO MYOPIA.

The patient when first seen, in 1875, was a little girl, ten years of age. She complained of headache. Under atropia the error of refraction was corrected with a 60 s, 60 c. Axis 90. This gave $V = \frac{20}{XX}$. The headaches disappeared and did not return until after she had gone for some time without her glasses, they having been broken. When the glasses were renewed, the headaches disappeared and she passed from observation. A short time ago she again returned, complaining of headache and inability to use the eyes. It was then found that there was myopic astigmatism. This was corrected with a suitable glass, and since then there has been no difficulty.

The case was discussed by Drs. Knapp, Seely, Hay, and Theobald.

The Society then went into executive session.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. W. F. Norris, of Philadelphia.

Vice-President.—Dr. Hasket Derby, of Boston.

Secretary and Treasurer.—Dr. O. F. Wadsworth, of Boston.

Corresponding Secretary.—Dr. J. S. Prout, of Brooklyn.

Committee on Publication.—Drs. O. F. Wadsworth, Hasket Derby, and G. Hay.

Committee on Membership.—Drs. John Green, George C. Harlan, A. Mathewson, Samuel Theobald, J. J. B. Vermyne.

Drs. Miles Standish, of Boston, John Van Duyn, of Syracuse, and S. O. Richey, of Washington, were

ELECTED TO MEMBERSHIP.

The selection of the place for the next meeting was left to the judgment of the Secretary, the time of meeting being the third Wednesday of July, 1885.

Adjourned.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, May 5, 1884.

WILLIAM HUNT, M.D., IN THE CHAIR.

DR. PANCOAST presented a patient with

COMPLETE DISLOCATION, BACKWARDS, OF BOTH BONES OF THE FOREARM.

This gentleman while riding a bicycle, fell and injured his arm. He came to Dr. Pancoast immediately afterwards, and he found a complete dislocation, backwards and outwards, of both bones of the forearm. The patient does not recollect falling on the palms of his hands, but thinks that he struck his elbow. The question is whether this could be a complete dislocation of both bones, and whether this could take place without fracture of the condyloid process, or rupture of the ligaments. He could not detect any crepitus. In Prof. Gross's *Surgery* it is said that there is only one recorded case of complete dislocation of both bones of the forearm backwards. This is given by Erichsen. It seemed to him that this case could be called one of complete dislocation. He could put his finger in the trochlear surface from which the olecranon had been pushed out. He thought that under these circumstances the condyloid process would be broken, yet he could find no evidence of this injury; the ligament, he thought, must have been ruptured. The difficulty of reduction in this case was opposed to the supposition that the coronoid process was broken. The dislocation was reduced under ether by extension and counter-extension, with direct pressure on the olecranon; pronation and supination being also employed.

In reply to questions, Dr. Pancoast said that the arm was rigid, and that the olecranon rested on the posterior surface of the epicondyle with the end of the radius looking directly backwards.

DR. BARTON said that a case was brought into the hospital with a backward dislocation of both bones of the forearm, which was reduced without difficulty under ether. Three days later the woman died from delirium tremens. At the post-mortem it was found that the lower end of the humerus had made its exit through a tear in the ligament, and it would therefore seem more appropriate to speak of this as a forward dislocation of the humerus.

DR. NANCREDE asked if Dr. Barton found anything in the ligaments which would prevent the reduction of a forward dislocation of the radius head. He was called to a case in which another physician had tried for an hour under ether to reduce such a luxation. He tried every conceivable plan without avail. He even used local pressure with a tourniquet. The bone could be pushed to a certain point, and beyond that it could not be moved. It seemed as though, when the bone

was forced back, the edges of the tear through which it had escaped were brought together. There was no swelling to account for the difficulty. Nearly every one has met with such cases.

Dr. Packard said that there are one or two points in reference to dislocations of the elbow which have not been sufficiently dwelt upon in the discussion. One is that very often, in the dislocation of the elbow, the joint is not rigid in its displaced position. He could mention six cases in which the arm was perfectly flaccid, and was reduced without any difficulty. He thinks that Dr. Hunt will recall a case which he saw with him some twenty years ago, in which they divided everything in the neighborhood of the joint, but the arm was perfectly rigid. It was impossible to start the bones in the slightest degree. In adults the fixation of the joint is apt to be far greater than it is in children. In children one of the great difficulties in the diagnosis is to differentiate between dislocation and separation of the lower epiphysis of the humerus. He means the articulating portion of the radius only, not the epicondyle or epitrochlear. This occurs sometimes, and is apt to complicate the case very much, not at the time, but it makes the results very unsatisfactory.

Dr. Hunt thought it was the common experience that the elbow bears less delay in reduction than does any other joint.

Dr. Packard said that he should have mentioned, in connection with the case referred to, that the luxation occurred about five hours before attention was called to it. When they saw it, swelling had taken place to such an extent that it was impossible to decide as to the exact nature of the injury.

Dr. J. Ewing Mears said that it is conceded that in certain forms of this injury, it is almost, if not impossible, to reduce the luxation. Would it not be well in such cases to cut down on the joint as for the operation of excision? This, he thought, would be more efficient than the method of dividing the tendons subcutaneously, which was adopted by Dr. Packard.

NEWS ITEMS.

The Cholera Epidemic.—The cholera mortality in France, for the week ending July 22d, according to the cable dispatches, was as follows:

	16th.	17th.	18th.	19th.	20th.	21st.	22d.
Toulon,	11	37	30	17	46	20	14
Marseilles,	53	43	58	35	57	35	57

The disease has spread, and cases are reported at Arles, Brignoles, Paris, Lyons, and Vienna. At Arles the deaths are said now to be averaging nine daily.

The Steamer St. Dunstan, from Marseilles, arrived in the Mersey on July 18th. Two deaths from cholera occurred on board during the voyage. The steamer was ordered to be placed in an isolated position, and all communication with the shore was forbidden. The ship was twice disinfected, and the stores which she took on board at Marseilles have been destroyed, and her water ballast has been pumped out.

Cholera Precautions in the United States.—At a meeting of the Cabinet, held on the 18th inst., it was decided to take prompt measures to prevent the introduction of cholera into the United States, and on the next day the President issued the following proclamation:

"While quarantine regulations are committed to the several States, the general government has reposed certain powers in the President, to be used at his discretion in preventing a threatened epidemic.

"Feeling it my duty, I hereby call upon all persons who, under existing systems in the several States, are intrusted with the execution of quarantine regulations to be diligent and on the alert in order to prevent the introduction of the pestilence, which, we all regret to learn, has made its appearance in some of the countries of Europe, between which and the ports of the United States intercourse is direct and frequent.

"I further advise that the cities and towns of the United States, whether on the coast or on the lines of interior communication, by sound sanitary regulations and the production of cleanliness, be prepared to resist the power of the disease and to mitigate its severity.

"And I further direct the Consuls of the United States in the ports where the pestilence has made or may make its appearance, to exercise vigilance in carrying out the instructions heretofore given, and in communicating to the Government of the United States any information of value relating to the progress or treatment of the disease."

On the same day the Secretary of the Treasury issued instructions to collectors of customs and other persons interested, to prevent, until further orders, the unloading of rags from infected foreign ports, and of rags which are suspected on good grounds of being infected, coming from any foreign port.

He also issued the following circular:

"In view of the presence of an epidemic of cholera, the existence of yellow fever, and the Oriental plague, abroad, the safety of the public health in this country demands the enforcement of rigid quarantine against the introduction of these diseases through vessels arriving at our ports. Therefore, in order to assist local authorities in the maintenance of quarantine as provided in Section 4792, Revised Statutes, the unrepealed portion of the Act of April 29, 1878, and recent appropriation acts authorizing the President to maintain quarantine at points of danger, the President has determined to establish, by means of the vessels of the Revenue Marine, a national patrol of the coast of the United States, so far as it may be practicable under existing law and consistent with the performance of the other duties confided to that service."

He accordingly directs "the Revenue Steamers to cruise actively upon the outer lines of their cruising grounds, and to exercise especial vigilance in speaking all vessels arriving from foreign ports, directing their inquiries, first, as to the port from which the vessel sails, and, secondly, as to the health of those on board at the time of departure, during passage, and at the time of hailing; and should the information gained indicate a condition of contagion or infection in the vessel or crew, or that the vessel has left a port at which contagious or infectious diseases were prevailing, her master will be directed to proceed for examination to the outer quarantine station provided for her port of destination.

"The following regulations will be observed relative to the inspection of vessels:

"If a vessel be found with sickness on board, or in a foul condition, she will be directed to proceed to the quarantine station indicated, and the revenue-marine officer will immediately notify the proper quarantine officer. In such case no person will be permitted to board the vessel until the medical officers in charge of the quarantine shall have given the usual permit.

"Should the pilot or master of a vessel when hailed report cases of recent or present sickness on board, the revenue officer will not board, but will send her immediately to quarantine.

"Quarantine officers will be recognized as follows, viz:

"Medical officers or acting assistant surgeons of the Marine-Hospital Service, in charge of Gulf, South Atlantic, or Cape Charles quarantines, or any officer of said service, on duty at any port on the interior rivers or the Great Lakes; and all quarantine officers acting under proper State or local authority."

PRECAUTIONS IN CANADA.—In the matter of the quarantine of vessels, the Dominion Department of Agriculture is taking every precaution. Instructions have been issued to quarantine stations to inspect all vessels arriving from Marseilles, Toulon, and London. At the Miramichi district, Dr. J. R. McDonald has been authorized to make a medical inspection of all vessels arriving in the ports of that district, for the reason that a number of ships arrive there from Mediterranean ports.

EUROPEAN PRECAUTIONS.—The health officers of London held a meeting, on July 18, for the purpose of organizing a hospital service throughout the city, so that in case of the appearance of cholera, the patients can be immediately cared for.

The Academy of Medicine of Paris, by a unanimous vote on July 17, decided that a land quarantine in France is impracticable. It also declared that the disinfection process is inefficacious and illusory, and urged the establishment of cholera hospitals at all large railway stations; and, in accordance with this decision, the fumigation of the railway stations at Toulon, Marseilles, and Paris has been discontinued.

The governments of Italy and Switzerland have agreed to coöperate in measures to prevent the introduction of cholera into their territories. Switzerland has expressed its willingness to guard the French frontier, in order to examine all persons and goods crossing it. Hospitals for the accommodation of cholera patients have been formed at Chiasso, Switzerland, and Luino, Italy.

Portugal has extended her quarantine to all European shipping.

The Spanish Government has strengthened the sanitary cordon in the Pyrences, and produce from Marseilles and Toulon will not be permitted to enter Gibraltar.

The Russian Government has ordered a strict guard to be maintained at the frontier railway stations against the introduction of cholera.

THE CHOLERA IN CALCUTTA is on the decrease, only seventy deaths having occured for the two weeks ending June 7th.

YELLOW FEVER.—There were twenty-nine deaths from yellow fever at Havana last week. No case of the disease has yet obtained a foothold in the United States so far as is known.

PENNSYLVANIA HOSPITAL FOR THE INSANE.—Dr. John Bassett Chapin, at present Superintendent of the Willard Asylum for the Insane, at Willard, N. Y., was, on July 16th, unanimously elected to succeed Dr. Thomas S. Kirkbride as Physician-in-Chief and Superintendent of the Pennsylvania Hospital for the Insane.

OBITUARY RECORD.—A cablegram announces the death at London, on July 21st, of Mr. CÆSAR HENRY HAWKINS, Sergeant Surgeon to the Queen. Mr. Hawkins, third son of the late Rev. Edward Hawkins, and grandson of Sir Cæsar Hawkins, first baronet, sometime Sergeant Surgeon to George II. and III., was born towards the close of the last century. After having been for a few years Lecturer on Anatomy at the school in Great Windmill Street, he was, in 1829, elected Surgeon to St. George's Hospital, where he lectured on Surgery. He resigned in 1861, was appointed Consulting Surgeon to St. George's Hospital, of which he was a trustee; was for some years an Examiner in Surgery at the University of London, and a member of the Court of Examiners of the Royal College of Surgeons, of which he has twice been president. Mr. Hawkins held several other professional appointments, such as President of the Royal Medical and Chirurgical and Pathological Societies, and on the death of Sir Benjamin Brodie, he was appointed Sergeant Surgeon to Her Majesty. He is the author of "Lectures on Tumors," and other subjects in the *Medical Times and Gazette* and has been a frequent contributor to the *Lancet*, and the *Medical and Chirurgical Transactions*.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 15 TO JULY 21, 1884.

WRIGHT, J. O., *Major and Surgeon.*—Assigned to duty as Post Surgeon, San Antonio, Texas.—*Par. 4, S. O. 87, Headquarters Department of Texas*, July 14, 1884.

HARTSUFF, ALBERT, *Major and Surgeon.*—Leave of absence extended one month.—*S. O. 79, Headquarters Division of the Missouri*, July 18, 1884.

MCELDERY, HENRY, *Captain and Assistant Surgeon.*—From Department of the Platte to Department of the East.—*Par. 12, S. O. 165, A. G. O.*, July 16, 1884.

EWEN, CLARENCE, *Captain and Assistant Surgeon.*—Assigned to duty as Post Surgeon, Fort Sidney, Neb.—*Par. 8, S. O. 58, Headquarters Department of the Platte*, July 11, 1884.

ELBREY, F. W., *Captain and Assistant Surgeon.*—Leave of absence still further extended six months on surgeon's certificate of disability.—*Par. 6, S. O. 161, A. G. O.*, July 12, 1884.

STRONG, NORTON, *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for two months, to take effect when relieved from duty in Department of the Platte.—*Par. 2, S. O. 68, Headquarters Division of the Missouri*, June 27, 1884.

WAKEMAN, WM, J., *First Lieutenant and Assistant Surgeon.*—Relieved from duty at Fort D. A. Russell, W. T., and assigned to duty as Post Surgeon at Fort Washakie, W. T., relieving Assistant Surgeon Norton Strong.—*Par. 9, S. O. 58, Headquarters Department of the Platte*, July 11, 1884.

APPOINTMENT.

CHARLES B. EWING, to be Assistant Surgeon, with the rank of First Lieutenant, July 5, 1884, vice Middleton, promoted.—*Mem. A. G. O.*, July 14, 1884.

ORIGINAL LECTURES.

DISEASE OF THE HIP-JOINT.

A Clinical Lecture,
Delivered at the Bellevue Hospital Medical College.

BY LEWIS A. SAYRE, M.D.,
PROFESSOR OF ORTHOPÆDIC SURGERY IN THE COLLEGE.

(Reported by Edward Develin, M.D.)

GENTLEMEN: The first case that I present to you today is that of a little child eighteen months of age suffering from hip-joint disease in the second stage. On account of the small size of the child when she was first brought to me, I deemed it inexpedient to attempt to apply the long hip-splint, and, therefore, directed her to be placed in the wire cuirass (Fig. 1) in which you now see her. When I first saw her there was an enormous abscess at the joint, which I believed, at that time, to be extracapsular. This was aspirated three times, in the hope that by this means, and by compression afterwards applied, the walls would become agglutinated, and thus all further trouble in regard to the abscess be done away with. I gave her the benefit of the doubt in this case, in order, if possible, to avoid an incision and the appearance of the resulting cicatrice from this treatment. It, however, was of no avail, the abscess still continuing to fill up. I therefore made a free incision down to the lower border of the abscess, by this means securing thorough evacuation of its contents; then washing it out thoroughly and inserting a rubber tube I maintained perfect drainage. As I remove this dressing, you observe that the parts are now in a healthy, granulating condition, and the limb is of normal size; perhaps somewhat smaller than the other, owing to its confinement.

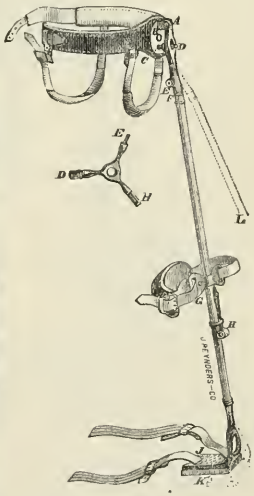
Having now removed all dressing from the limb, I carefully lift it up from the cuirass, at the same time that I make a slight traction upon it. This you must be careful to do, otherwise you will cause pain by your manipulations. As I now hold the leg in this position, with my other hand under the thigh, I can make quite free motion within the joint in all directions without causing pain, as is shown by watching the face of the child.

I see no reason, therefore, why we should not secure the most satisfactory results in this case, and restore this child with perfect strength and motion in this now diseased limb. Before a year has expired I hope to be able to apply the long hip-splint, which I here show you (Fig. 2), in order that the child may secure all possible benefit from out-door exercise.

In relation to the wire cuirass in these cases of very small children suffering from hip disease, in which the long splint cannot be applied, I cannot speak too highly. By means of the screws attached to the footplate you can secure any amount of traction you desire, making your counter-traction, as is done in this case, by passing your roller bandage under the perineum and up over the handles of the instrument, which, you observe, are midway between the thigh and shoulder. In this position, the anus being directly over the opening in the back of the instrument, the child can relieve its bowels without disturbing its position, and the parts can be cleansed by the mother without soiling the clothing or person of the child, the instrument at that point being covered with rubber cloth. She can, as she is now

FIG. 1.

FIG. 2.



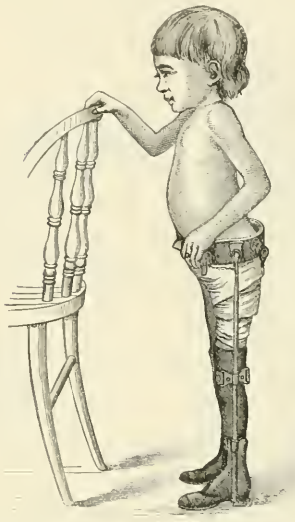
secured, be placed in the upright position as you now see me take her. In this position she can be placed by the window, in order to secure the benefit of the fresh air when the mother is not at liberty to take her out. The facility with which I can handle the child as she is now secured, without causing her pain, cannot fail to convince you of the advantages to be gained by the use of the cuirass in those cases in which the child is too small for the hip-splint to be applied.

[Note, thirteen months after.]—The child has now been wearing the hip-splint for some months. Three months ago she suffered from a severe attack of pneumonia, followed by acute nephritis. The attending physician gave his opinion that she could not possibly survive. At the present date, however, she has fully recovered, and is able to walk around out of doors, and

is brought to the city to my office once a week to allow dressing of the abscess. Prior to the attack of illness I have just mentioned a second abscess formed at the thigh, which I incised, freely washing out its contents, and dressing, as is my usual custom, with oakum and Peruvian balsam.

There is now excellent motion in the hip-joint, the progress of the disease having been arrested in spite of the unfavorable conditions induced by her recent illness. The prognosis is most favorable in this case. Fig. 3 shows condition of child at the present time, with long hip-splint applied.

FIG. 3



In applying the long hip-splint the leg should, first, be carefully washed, in order to remove all excretions upon the skin, which might interfere with the adhesion of the plaster used in its application. This having been accomplished, I then take two long strips of mole-skin plaster, about two inches in width, reaching from the upper part of the thigh on either side to just above the ankle. At the lower end of each strip you will notice there has been a buckle attached. Placing these strips of plaster on either side of the leg, I then take an ordinary bandage and bind very tightly around the leg from the ankle to the thigh. This bandage is to be removed in a few moments, but my object in applying it tightly, is to secure firm adhesion of the plaster to the skin; you notice that the better to secure this I am now rubbing over the plaster outside of my bandage, in order to secure this adhesion.

Now, removing this bandage you observe the plaster is firmly adherent. I never apply artificial heat to the plaster unless the air in the room is very cold; as I have so often seen the adhesiveness of the plaster entirely ruined by warming over a spirit-lamp, and the dressing required to be renewed in a few days; whereas the dressing which I am now applying will, I trust, remain for weeks, or even months.

I then take a flannel bandage, and commence to bandage the foot, gradually passing up the limb until I reach the upper third of the thigh; at that point I reverse the ends of my adhesive strips over the flannel bandage, and secure them with a few turns of the roller, thereby materially assisting in keeping the dressing in place. This dressing is precisely the same as that which was applied to the child one year ago, when she was placed in the cuirass. I should, therefore, have applied the splint without redressing, had it not required it. It has, however, given me the opportunity of showing you the manner in which I apply the same, preparatory to applying the long hip-splint.

You will notice that this long splint consists of a pelvis belt passing around the pelvis in such a manner that the *upper* edge of the belt is on a line with the crests of the ilia. There are also two perineal bands. Now passing from this pelvis belt at the side, in a line with the great trochanter, we have this side rod which is hollow and cylindrical; half way between the knee and ankle this rod ends, and admits a smaller rod which passes into it, and is regulated by a ratchet and key; the foot-piece at the lower end of this rod passes under the shoe, and a small leather strap there inserted is secured on either side by the buckles which are attached to the adhesive plasters secured as I have just shown you. There is also at the knee, you observe, a buckskin pad to assist in maintaining the leg in position; and when necessary a joint can be placed in the shaft of the splint at the knee, to allow of flexion when sitting down. This may be done when the active progress of the disease has been arrested and recovery approaching. I wish to draw your attention to the position of the perineal bands, as the instrument-makers will attach them at almost every conceivable place upon the pelvis belt where they are not wanted. Now, posteriorly, as you observe, these straps are wide apart, passing over the gluteal muscles. But anteriorly you notice they are much closer upon the belt, being only about three inches apart, and passing directly up on either side of the symphysis pubis. If the bands are placed widely apart anteriorly, they make compression upon the femoral vessels and press the thighs outwards. At the same time, the traction is not brought to bear upon the desired point.

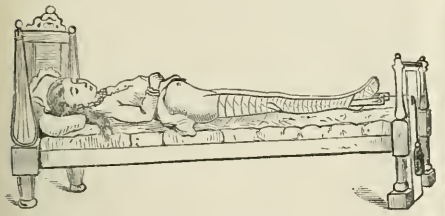
Having now secured the instrument upon the child, our next point is to make extension. This is accomplished by means of the ratchet and key here shown you. The extension is to be made to that point at which your patient states he feels *comfortable;* there you must stop and secure your extension by means of this little sliding catch upon the rod. Do not judge your extension when applied the next day by that made upon the preceding; do not count or mark the holes in the straps or notches upon the instrument, and take that as your guide; for leather will stretch, and you may not apply the instrument exactly as you did before; therefore, you will fail to secure relief if you make your extension to any set marks. *You must always be guided by the feelings of your patient.*

When you have applied one of these instruments to a child, and instructed the parents as to its mechanism;

you will often have them ask you to mark upon it how far they are to key out the rod in order to make extension. You must impress upon them the utter uselessness of this method, and insist upon extension being made until the patient states, that at one particular point of the extension he feels most comfortable.

At night when the child goes to bed the splint is to be removed, and the weight and pulley applied to the foot, as I have before stated. (Fig. 4.) In some cases, however, you may find that the patients will state that they

Fig. 4.



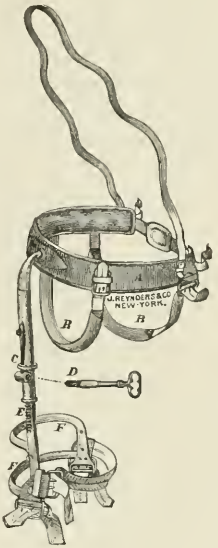
are more comfortable with the splint than with the weight and pulley, and will ask to be allowed to wear the splint in bed. I know of no reason why they should not do so if they desire, but, as a rule, the weight and pulley affords the same relief as the splint when it is properly applied. In such cases, therefore, examine carefully your night extension apparatus, and see that the bed is raised sufficiently to secure counter-extension; for it is on these slight details that the success of your treatment depends.

I probably could not choose a better time than the present to explain to you the application of the short hip-splint, so that you may compare the two instruments and their application.

The short hip-splint (Fig. 5), you observe, like the long one has a belt which completely encircles the pelvis. From the side of the splint passes down a rod which is composed of two pieces sliding within each other, and regulated by a ratchet and key as extension may require. This side rod passes down within a distance of one and a half inches above the condyle, so that the two flat curved bars which pass from this portion of the rod over and in front of the thigh cannot by any possibility press down upon the patella if the instrument is properly adjusted. There are also, as you notice, *two* perineal bands, as in the long hip-splint, and a strap going over the shoulder from the outer ends of the pelvis belt, to keep it at right angles with the body. At the ends of the lower bar, which passes in front of the thigh above the patella, are two buckles which are to secure the splint in position, from a piece of stout webbing attached to the plasters, which I will now show you how to apply.

The short splint is to be removed at night, but we must still maintain our traction upon the limb: to do this, the weight and pulley is applied as I have shown you in illustrating other cases. There is, however, a difference in the form and application of the adhesive plaster to the leg in this splint. I first take two long strips of adhesive plaster, which pass up the leg as in the long splint, but with this difference: they do not extend more than two or three inches above the condyles of the femur. These are secured with the roller bandage,

Fig. 5.



as I have before described, and are for night extension only. The next thing for us to do, is to apply the plasters

Fig. 6.

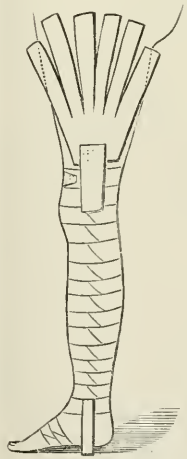


Fig. 7.

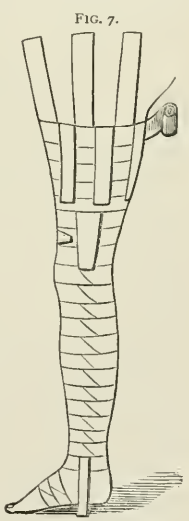
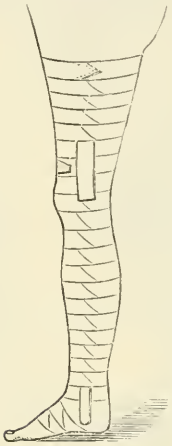


which secure the splint in position. These consist of two broad fan-shaped pieces of plaster split into five or six

tails (Fig. 6), except at the lower narrow portion, which is not cut. At that point about six inches of stout webbing is sewn firmly to the plaster. Having prepared these in this manner, you place the lower portion holding the tab, three inches above the condyle on either side; then carry the tails of the plaster up the thigh. My assistant then holding these in position, I commence at the lower end with a roller bandage, leaving my pieces of webbing outside and passing upwards, reversing the ends of the plaster over my bandage as I reach the upper part of the thigh (Fig. 7), and then, with a few turns of the bandage, I secure these reversed ends, and the dressing is complete. (Fig. 8.) In order to make

FIG. 8.



the plaster more firmly adherent, I then rub it into the skin by pressure upon the outside of my bandages.

We are now ready to apply the splint, although when practicable I prefer to wait a few hours, as the plaster has then become more firmly adherent, and is therefore less likely to slip when I make extension on the limb.

The pelvis belt and perineal bands are adjusted as in the long splint; before fastening the perineal bands, however, the splint is brought into place, and the tabs on either side of the thigh above the knee are passed over the roller and secured by the buckles on the inner and outer side of the curved bar which passes over and in front of the thigh just above the knee. These being securely fastened, the perineal bands are made secure, and the shoulder strap fastened so as to give equal pressure upon the outside perineal band, and I am then ready to make extension. This is done by the ratchet and key in the side rod; making the extension to the point where it affords the patient the most relief, as I have before explained to you when applying the long splint.

CASE II. *Hip disease: second stage.*—Female, aged twenty-one years. This patient comes from Connecticut. She states that two years ago she suffered from sciatica, the pain being intense in the left side, hip, and knee; at that time she was confined to her bed for five weeks, since that time she has been lame and unable to walk without crutches.

You observe that the patient bears the weight of the body entirely on the right limb; the left limb is flexed at the thigh and knee, the toes being turned outwards, this deformity would indicate disease of the hip-joint advanced to the second stage; namely, effusion within the capsule. The gluteo-femoral crease upon the left side has entirely disappeared, giving the natis upon that side a flat appearance, this, also, is characteristic of hip disease, although observable in other deformities. The moment we attempt to invert this left foot, you observe it causes a spasm of pain; by this action the capsular ligament was rendered tense around the neck of the femur, and by its pressure upon the inflamed parts induced this spasm. We now take hold of the thigh just above the knee, and make traction upon it *in the line of the deformity;* I wish you to watch carefully the manner in which this is done, as some gentlemen by their manipulation increase the severity of the disease by making rude traction upon the limb, omitting to make their extension in the line of the deformity, and by such omission increase the pain and irritation at the seat of disease. There is no necessity to cause pain in your extension; it is just the reverse of that, as you can now see by the expression of the face of this patient; apply your force in such a manner as to relieve the inflamed parts from pressure; so that if by this means you relieve your patient it is equally of diagnostic importance as though you had caused pain. I can tell the moment that relief is afforded, by the relaxation of the muscles beneath my fingers; and now with the limb extended in this manner we can make slight motion in the joint without causing pain, but the moment the extension is released the muscles instantly assume their rigidity, and, as you observe, it is impossible to move the limb in the least degree without causing pain, and the whole pelvis moves as if the joint were anchylosed.

It is therefore necessary to place the limb in the extended position, and retain it there with traction maintained by artificial means, until the fluid within the joint is absorbed, keeping the patient in bed, and making the extension by means of the weight and pulley, a sling or cushion being used to support the leg in order that the extension may be made in the line of the deformity, the limb being gradually brought parallel with the body as the effusion within the joint subsides; a blister in the meantime being placed behind the trochanter major and repeated as often as necessary. After the effusion has been absorbed and the limb brought to the normal position, my long or short splint is then to be applied to maintain the extension, and thus prevent the attrition of the articulating surfaces. The patient can then go out of doors in order to exercise the limb, and secure the benefit of the fresh air, so that her general health will not suffer in any degree.

[Note.]—This patient was placed in the hospital and extension maintained for three weeks as stated above, the effusion within the joint having then been absorbed sufficiently to allow of the application of the splint. Her improvement was so rapid and satisfactory, that

I applied the short hip-splint in this case, as I judged it would fully answer all purposes required. The following week she left for her home in Connecticut, still improving; the treatment to be continued by her attending surgeon.

Case III.—This child which I now bring before you was presented at our clinics one year ago, suffering from disease of both hip-joints; the disease being caused by a fall in which the legs were thrown widely apart, and occurring some three years previous.

A year ago, when this girl was presented to us, the left leg was in the second stage of hip-joint disease, being flexed at the thigh at an angle of 45°, strongly abducted and rotated outwards with eversion of the foot, giving us the characteristic deformity of the second stage of the disease. The right hip-joint had probably sustained less injury than the left, the disease in this joint being in the first stage.

I at that time directed that the child be placed in bed and traction made upon both limbs by means of the weight and pulley, it being applied to either limb in the direction of its deformity; counter-extension being secured by the weight of the body, by means of raising the foot of the bed six inches.

This treatment has been faithfully followed out, and with the most satisfactory results in the right limb, as a complete recovery has been secured and we have now perfect motion within the joint. The disease in the left hip-joint, however, had reached such an advanced condition of the second stage that it could not at once be arrested, and rupture of the joint capsule followed a few days after I saw her. In consequence of this condition we have here a slight arrest of the growth of the limb, and in all probability some absorption of the bony structures of the joint itself.

I can now, while making traction upon the limb, bring it to a right angle, with adduction, abduction, and rotation without causing any pain; thus showing that a cure can be effected in this case with probably perfect motion, although, of course, the limb will be shortened. Since treatment was first commenced in this case the child has grown four inches in height; the disease, however, when I first saw her had advanced to such a stage that the effusion within the joint has since caused rupture of the capsule, and the fluid has now escaped into the surrounding tissues; so that the disease in this left leg has reached the third stage, giving us, when extension is discontinued, flexion and adduction of the limb with rotation inwards, and inversion of the foot. Now, when the rupture of the capsule occurred the child experienced relief from pain, and there also occurred, a change in the position of the limb, it then assuming the deformity of the third stage of hip disease, namely, adduction of the thigh with inrotation of the limb and inversion of the foot.

I have told you that the capsular ligament of the hip-joint has been ruptured in this case; hence we have then the fluid which it previously contained, flowing out into the surrounding tissues, resulting in the formation of an abscess with the accumulation of a large quantity of pus; this abscess we will now aspirate, and, if its contents are sufficiently fluid to pass through the needle, we can remove this matter, which is a foreign body. (The aspirator was then used, one ounce of pus being withdrawn.) You observe that as I withdraw the needle I slip my thumb over the wound and then close it with a piece of adhesive plaster, thus preventing the admission of air to the cavity. We now take a roller bandage and bind firmly around the thigh and pelvis so as to bring the walls of the abscess in apposition; and it is possible that we may by this means cause adhesion of these walls. In this case, as the contents of the abscess were easily evacuated, we may eventually effect a cure by this means, and thus avoid making a free incision; whereas, had it been a semi-fluid mass containing flocculi and sloughs of connective tissue, our best treatment would then be freely to open and wash out the abscess.

We will now apply the long hip-splint, the leg having been brought perfectly straight by extension and counter-extension; the child can then go out of doors and secure the benefit of the fresh air, by this means keeping up her general condition. It may, however, be necessary to aspirate this abscess more than once, and if this method fails, a free incision should then be made, as I have before stated.

Case IV. *Hip disease: third stage.*—The child which I here present to you was also sent to me from Connecticut, and I bring him here to show you the deformity which characterizes disease of the hip-joint in the third stage, and which the rupture of the capsule and absorption of the osseous structures will produce. He is now four years of age, and the parents attribute this difficulty to falling from his bed, shortly after which he first commenced to complain of pain in his knee. He was afterward taken to the Massachusetts General Hospital, where he was treated with a fixed apparatus for disease of the knee-joint.

As he now lies upon the table, my assistant holding the pelvis perfectly still, with the spinous processes of the vertebral column touching the table, we begin to realize the extent of the deformity here produced. For you notice, in order to place the back and pelvis in their normal position, and which they now represent, I am compelled to adduct and inrotate the limb across its fellow just above the knee over the thigh, thus giving us inversion of the foot, and at the hip you will notice an undue prominence of the trochanter major, arising from this same inrotation of the limb. Now, as long as I maintain the limb in this position, at the same time making slight traction upon it, he is free from all pain. This then is your course to pursue; you yourself cannot hold the limb for any length of time, but you can apply mechanically such means as will secure the same result.

If now my assistant releases his hold upon the pelvis and I bring this diseased limb parallel with the other one, and press the popliteal space upon the table, you notice that as soon as I commence this the back begins to form a complete arch, at the same time the pelvis tilts forward in order to accommodate itself to the deformity I just now showed you. This present position could be maintained only for a few moments without causing great suffering to the patient, and that, of course, I wish to avoid. You notice that, as I now relax my long hold, the leg commences to rise and is gradually drawn over the opposite limb, while the back sinks down to its normal position. The patient knows very readily the position in which to place himself in order to secure the most ease, and thus it is in the de-

formed position which I first showed you, that he will naturally place himself.

What we want to do is to find the exact line of the deformity; to do this you must fully understand the anatomy of the human body. If there is nothing abnormal, the thigh can be brought down until the popliteal space touches the table and the pelvis remains perfectly still; but now in trying to make the same motion with the diseased limb and yet retain the pelvis in the same position, we are compelled to flex, adduct, and invert the limb; the popliteal space cannot therefore be brought down to touch the table without the arching of the spine and tilting of the pelvis. This is a typical case of hip-joint disease in the third stage.

This child has been sent to me to have the long extension splint applied, but in his present condition it is not applicable. It is now necessary to place the child in bed and secure extension by means of the weight and pulley in the line of the deformity, gradually changing that line, as I have before stated. By this means, in a few weeks you may perhaps bring the limb straight; you can then apply the long splint to the greatest advantage. Now, it may be, that this abscess at the joint will require to be freely opened. I will, however, try the aspirator first and endeavor to secure absorption before resorting to this operation.

If, after proper extension has been applied and thorough drainage of the abscess has been secured, the disease still progresses, you will then need to exsect the hip-joint.

In this case I shall send the child to his home, giving such suggestions to the medical attendant in charge as the treatment which his condition may require.

The instruments which I have to-day shown you can be procured from my instrument-makers, Messrs. Reynders & Co., 303 Fourth Avenue. I mention this, as so many physicians coming from a distance frequently are at a loss to know where they can secure the splints which I use.

ORIGINAL ARTICLES.

ON THE CHLORIDE OF GOLD AND SODIUM IN SOME NERVOUS AFFECTIONS.[1]

BY ROBERTS BARTHOLOW, M.D., LL.D.,

PROFESSOR OF THERAPEUTICS AND MATERIA MEDICA IN THE JEFFERSON MEDICAL COLLEGE OF PHILADELPHIA.

IN that curious accumulation of mediæval learning, *The Anatomy of Melancholy*, gold is mentioned as a valuable remedy in the treatment of that affection. The eccentric author got his notions from the alchemists, and the physicians of the chemical school then rising into prominence. From the earliest times, gems and precious stones, and, to a less degree, the noble metals, were supposed "to free the mind, and mend the manners." Thus Chaucer, who died in the year 1400, æt. 72, in his Canterbury Tales, describes in the Prologue "a doctour of phisike," who

> "Knew the cause of every maladie,
> Were it of cold, or hote, or moist, or drie,
> And where engendred, and of what humour,
> He was a veray parfite practisour."
> . . . . .
> "And yet he was but esy of dispence!
> He kepte that he wan in the pestilence,
> For gold in phisike is a cordial;
> Therefore he loved gold in special."

The Arabian physicians, afterwards the Italians, and later still the Montpellier school, recognized the virtues of gold in certain mental and nervous diseases. The best account of gold, from the historical standpoint, and, also, of its physiological and therapeutical properties, is that given by Trousseau and Pidoux. These authors availed themselves freely of the labors of Chrestien, of Montpellier, whose researches have proved the most important yet undertaken.

Gold, in the form of powder, and, also, of chloride, was the subject of investigation by Hahnemann, whose "provings" corresponded, in the main, with the ideas then entertained of the actions and uses of gold. Since then, the homœopathists have employed gold in two classes of cases: hypochondriasis and increased discharge of urine. I once heard an original homœopathist, a high-potency person, testify regarding the happy influence of the 30th dilution of gold on the mental condition of an old man affected with senile dementia. When the astute attorney on the other side, got the homœopathic doctor to make a calculation of the quantity of gold actually received by his patient, the jury wore an incredulous look, very depressing to the opposing counsel.

From the various sources of information now available, chiefly clinical, we learn that the preparations of gold possess those properties formerly entitled *alterative*, and now usually designated by the phrase *promoting tissue-metamorphosis, or metabolism*, and the power to give stability to nervous matter, or the antispasmodic property. There are three several heads under which it will be convenient to group for my purpose the therapeutical powers of gold and its preparations, quite irrespective of its supposed physiological actions:

The so-called alterant effects;

The actions on the nervous system;

The urino-genital properties.

Before undertaking to present the details under these several heads, it may be best to say something of the preparation used. I have always preferred the double chloride of gold and sodium since I learned how little diffusible the chloride is. Injected subcutaneously in animals, the chloride seems not to diffuse through the vessel-walls, and when introduced into the blood tends to clog the kidneys. On the other hand, the double salt is readily diffusible. I have no experience with metallic gold or the oxide. Notwithstanding the chloride is so little diffusible, when taken into the stomach, effects are produced. It is probable that in the reactions which ensue the double chloride—of gold and sodium—is formed.

The usual dose of the gold and sodium chloride is one-twentieth of a grain. In this quantity twice or

[1] A preliminary note read before the American Neurological Association.

three times a day, it appears to have, as its primary action, the power to promote constructive metamorphosis, to improve the globular richness of the blood, and to increase tissue-strength. However, kept up for a time, tissue-changes become more rapid, and waste occurs in excess of repair. The tissues yielding most readily are, as might be expected, the connective, and especially those of pathological formation. Hence the utility of this remedy in *sclerosis*, whether nervous, hepatic, or renal. Especially in posterior spinal sclerosis, and in chronic interstitial nephritis, have I found the gold salt very efficacious. I am far from believing that lost parts may be restored, although some of my critics appear to think my credulity limitless. If used in locomotor ataxia, early and persistently, it has seemed to arrest the disease. It is true, since the publication of Strumpf's results with the faradic brush, I have not failed to make use of this method, but that it alone will stop the morbid process, I do not find. Before the electric brush had been employed systematically, I had witnessed the best results from gold and sodium chloride. During the last ten years, I have seen many cases in consultation, but of five in my immediate charge which I have followed, and in which the treatment was begun with the onset of the second stage; in three the disease seems not only to be arrested, but the condition improved. The knee-jerk, however, remains absent or feeble. The others are manifestly improved. Thus far, no persistent gastric or intestinal disorder has been caused by the remedy.

Excellent results have followed the use of the gold chloride in many cases of fibroid kidney, not only in my own hands, but in the care of other practitioners. Unquestionably the homœopathists, guided in the use of this agent by the symptom—increased urinary flow, have had good results from the first dilution, but this topic is foreign to my present purpose.

There is a form of hypochondriasis, coincident with the onset of degenerative changes in the cerebral vessels—and it may be dependent on these changes—in which the gold and sodium chloride is very effective. It must be persistently used, and after a time the uneasiness in the head, the vertiginous and other abnormal sensations subside, the mental depression at the same time clearing up. Dr. Bauduy, of St. Louis, kindly informs me that he has had the same good effects. It seems to me that the ancient notion that gold is a "cordial" to the mind in cases of melancholy, is also supported by modern experience.

In certain affections characterized by spasm, as asthma, laryngismus stridulus, and singultus, this remedy acts surprisingly well sometimes. A physician with large experience in a malady which I do not see at all now-a-days—pseudo-croup, or laryngismus—informs me that he employs no other remedy, and his patients get speedy relief. There are various cognate affections in which, no doubt, it will be found in a high degree useful.

The same powers render gold a remedy of great value in certain urino-genital affections. I have referred to chronic interstitial nephritis. I could enumerate many instances of the more chronic cases of albuminuria, in which the curative effects of this remedy have been most conspicuous; but I am here concerned with the merely nervous affections. There are certain cases of sexual debility, accompanied by an extreme degree of hypochondriasis, which are amongst the most difficult and unsatisfactory with which we have to deal. No remedy has seemed to me so serviceable as this in this troublesome condition of things. In simple sexual debility, its administration promotes activity. In dysmenorrhœa with scanty menstruation, and in chronic metritis, accompanied by these symptoms, the persistent administration of gold and sodium chloride has done much good.

I present these notes now, in advance of more elaborate treatment, to awaken a more general interest in the actions and uses of gold. My observations indicate the direction in which this remedy promises to be useful, but wider and more varied experience is necessary to fix its real position. That it possesses very valuable powers, is certain, but it remains to be seen how far my belief is justified in the results of many cases seen under diverse conditions.

TREPHINING FOR INSANITY, CONSEQUENT UPON A DEPRESSED FRACTURE OF THE SKULL.[1]

By WILLIAM A. BYRD, M.D.,
of Quincy, Illinois.

La Motte, in 1705, trephined a patient for epilepsy, according to Dr. Gross; then that method of treatment slumbered for ninety-nine years, to be revived by Mr. Cline, of London, but the operation did not come prominently before the profession until Dr. B. W. Dudley of Lexington, Kentucky, published, in 1828, five cases he had operated upon for that disease.

Insanity as a sequel to epilepsy is not so rare as to cause, in my belief, the application of any remedy for it when resulting from epilepsy, or from such a cause as would produce epilepsy, to be looked upon as irrational practice. Yet when I searched the works on surgery in my possession, written by some fifteen different distinguished gentlemen, I found trephining for insanity from traumatism of the skull mentioned by but one, *Gross' System of Surgery*, 6th ed. vol., ii. p. 89, as follows: "Prof. Briggs had, up to 1882, trephined the skull for traumatic epilepsy in 28 cases, with complete recovery in 22, partial relief in 3, and no benefit in 1. For insanity caused by injury of the skull, he performed the operation in 2 cases, in one successfully, and in one followed by death." I wrote to Dr. Briggs, who kindly answered as follows:

"The cases have only been reported in my clinical lectures, which are published from time to time in our journal. I will send you the manuscript notes of the lecture in one of the cases, taken by a student. The other case was that of a little boy whose photograph I send you, exhibiting the seat of fracture, etc.

"He recovered his faculties after the operation. His symptoms were those of furious mania; fighting,

[1] Read before the American Surgical Association, May 2, 1884.

biting, and scratching every one with whom he would come in contact. Having a constant disposition to escape from his parents and hide himself. There was a peculiar disposition in this case, as well as in the first, and, also in another which I have since operated on, of keeping the head lower than the body. The favorite position of this boy was with his body bent over a chair, the head resting on the floor. I have only operated upon one case since my report to Dr. Gross. The case was that of a man who had received a gunshot wound just above the ear, fracturing and displacing the bones in an irregular manner. The removal of the point of irritation relieved him of his lunacy. When I meet you I will give you the cases in full, so that you can utilize them."

The report of the lecture of Dr. Briggs, describing his fatal case, reads as follows:

"The patient is a young man who, before his affliction, enjoyed good health, but his condition now is such as to excite the warmest sympathies of even the coldest among us. Five years ago he received a severe blow from a stone, on the skull, fracturing the parietal bone, a little below the protuberance, and to the right side, producing a broad, depressed fracture. Since that time he has degenerated into a condition of lunacy. His imbecility is so great that absolutely he can do nothing. Left alone his head hangs, his hands fall listlessly, and the vacancy of his face tells of the deep gloom that has settled upon his mind. He eats mechanically. All his functions are performed after a fashion, nor, indeed, can it be said with certainty that he is conscious of anything. At times, however, he becomes furious. During these fits he raves like a madman, and is so dangerous that handcuffs and other mechanical appliances have been found necessary to restrain him. As these attacks wear off, he relapses into his former condition of complete imbecility, so that, while he does exist, we may say that he does not live, that he merely vegetates.

"Applications ere now have been made to me to operate for his relief; but after examining him, and carefully reviewing his case, I decided that he was not a fit subject for the operation. Recently his condition has become so much worse that his family were induced to make another application, and at their urgent request a consultation of four of the faculty was held to consider the case. The decision was to operate with the full understanding, by these interested in him, that the remedy was a desperate one and only warranted by his deplorable condition.

"I cannot say that I think he will be benefited; it is one of those cases in which I cannot venture an opinion. But you saw the case on which I operated last month, and how great was the relief. True, that was a comparatively recent case, while this is an old one. And herein lies one of the chief dangers, for the circulation in the brain having accommodated itself to the abnormal condition of the parts, it is again disturbed by the operation, and again has to reaccommodate itself to the new order of things; and is required to do this in an abnormal and depressed condition of the system.

"Again, the patient himself cannot help us. He has no will-power, nor has he any thought for himself, or any consciousness of his condition. And, finally, he has but little vitality. His whole system has been depressed for a long time, and it may be that he has not even sufficient recuperative energy to rally from the immediate shock of the operation.

"He may be greatly benefited; I trust that he will be; he may recover from the operation, but with his condition unimproved; he may die during the operation, or he may die from its later effects.

"Thus you have the case before you. You see that it is one that no man would seek, but rather avoid as long as he could with justice. Still, after the operation has been decided as warrantable by a number of his professional brethren, a true surgeon could not fail to see his duty. Hence, it is with a full sense of the gravity of the case, and with a due appreciation of the solemnity of the occasion, on the issue of which hangs so much for the patient and his family, that I now proceed to operate."

The skull was then trephined, four crowns of bone being taken out, and the intervening portions of the bone cut out with the bone-nippers. The bone removed included all of the depressed portion:

"The operation was carried out as indicated, the patient being under ether, and the carbolized spray being used continuously. Two small branches of the occipital artery were ligated by Prof. C. S. Briggs, who, together with the hospital staff, assisted in the operation. Very little blood was lost, and the dura mater was untouched. A swall wisp of carbolized tow was placed in the wound to keep it partially open, thus permitting free drainage. The flap was secured by a single suture. A carbolized compress of tow was then applied, and lightly confined by a bandage. The patient was finally placed in the strait-jacket so that he might not do himself any injury on returning to consciousness.

"December 14th. I have to announce to you that the patient whom I trephined for lunacy is dead. The operation in every respect was performed in a correct way, and for a time after he appeared to be doing well. The next day he suddenly became much worse; had a rigor followed by great depression, but no fever, and he died suddenly that night."

I have reproduced nearly the whole of Prof. Briggs's lecture for its lucidity of style and correct reasoning. Many points have been dwelt upon by him that will not be necessary for me to consider a second time,

September 11, 1883, Mr. John P. B., of Colchester, Illinois, consulted me in regard to the advisability of having an operation performed to relieve his wife of insanity. He was accompanied by his wife and her father. The lady was a brunette, thirty-one years old, well nourished, of prepossessing appearance, and medium size. She had been insane for five years without any prolonged lucid intervals. For the last two years she had been in the asylum at Jacksonville. Eighteen years before she had been kicked by a horse, causing a depressed fracture of the skull at about the centre of the right frontal eminence. The depression was about an inch in length running diagonally downwards toward the nose. She recovered rapidly from the injury, there being at no time any symptoms of compression. In time she became somewhat erratic in her disposition, and gave evidence of being easily disturbed in her sleep. Still she made fair progress in her studies and became a good housekeeper. She married and had five children, three of them being born after she became insane. She was very seldom violent in her insanity, talked incessantly and used the most obscene language conceivable. The insanity had come on slowly and had been progressive. Her family and other physicians had advised the husband and father to remove her from the asylum and try to have her cured by an operation.

Sept. 13, 1883, at Blessing Hospital, in Quincy, she was brought under the influence of an anæsthetic, composed by measure of one part of ethyl bromide, three parts of chloroform, and four parts of alcohol, given by Dr. Charles Wesley Rook, and with the assistance and in the presence of Drs. I. T. Wilson, R. Woods, C. B. Ellis, and H. Hatch, the depressed portion of the skull was removed by taking out three pieces of bone with the trephine from a triangular space including the depression. The bone in the spaces between the openings made by the trephine was removed with the bone-nippers, and the edges of the opening rounded off and smoothed, making a circular opening in the skull of about an inch and a half in diameter. The bone was nearly half an inch thick, whereas, normally, at that place it is very thin.

The integuments that had been raised by a T-flap were brought down and together with catgut sutures, except at the lower angle, where a small rubber tube was inserted for drainage. She rested well the day following the operation in bed. The next morning, Sept. 14th, she was up and dressed, and but slightly incoherent.

From this day until Sept. 30th, she was perfectly rational and coherent.

On the evening of the 30th, she was excited, but not obscene or wild. The wound had healed perfectly; there had been no fever or other untoward circumstance at any time during the progress of the case.

On the morning of October 1st, her husband came to take her home. When she saw him she became very greatly excited and incoherent, using very obscene language, but at times would appear quite rational. He insisted upon her going home with him, much against my will as I felt that she needed still further the attention she could only get from trained nurses. After her arrival at home her husband wrote me that she became quite unmanageable, and continuing so, I advised that she be sent back to the insane asylum at Jacksonville, which was done.

The subjoined letter from Dr. Carriel will give an idea of her condition at the present time:

"Replying to your inquiry, I will say Mrs. John P. B., is now, and has been since her return, much deluded, and disturbed in mind: in fact, she has not been as well since her return as she was before leaving. I do not attribute this condition as resulting from the effect of the operation, but as the natural tendency of the disease. I see little reason to hope she will ever be better"

Thus there are reported in this paper four cases, all that I can learn. Of this number one died, one improved for a very short time and then became progressively worse, and two entirely recovered. The record, though short, shows, I think, that the operation of trephining should be resorted to oftener than it has been heretofore, and much earlier. The hope of recovery from earlier operative procedure is good and the condition of hopeless insanity is such that not one of us but would personally be willing to submit to any procedure for cure.

ON THE USE OF THE OBSTETRICAL FORCEPS AS A SPECULUM AND PROTECTOR TO THE VAGINA IN OPERATIONS UPON THE FŒTUS IN UTERO.

By JOSEPH PRICE, M.D., and G. G. FAUGHT, M.D., of Philadelphia.

While fully subscribing to Baudelocque's dictum, that "the forceps has been more injurious than useful to woman," we are persuaded that it is the abuse, rather than the intelligent use of them, that has made this saying possible. We might have some hesitation in adding to the already seemingly replete literature of the obstetrical forceps—in which every obstetrician, and many not laying claim to such a title, has been in print with instructions how, when, and where to use them; we might be deterred by the seeming self-sufficiency of the mass of the profession, as shown in the societies by the levity with which questions relating to their use are treated, from claiming for them a use in addition to that of tractors and compressors; were it not that we find the records of gynecology scored over and over again with cases, the sad history of which, is the result of their reckless and unintelligent use.

The late Dr. John Parry gives the mortality of craniotomy as 37½ per cent.; according to Dr. Agnew (*Surgery*, vol. ii. page 821), "a fatality quite as great as that resulting from Cæsarean section." As a careful perusal of the writings of Schroeder, Tait, and others, shows how often this operation is followed by genital fistulæ, we have good reason to believe that lacerations and contusions of the soft parts are no mean factors in accounting for this heavy mortality.

The design of the present article is to call attention to the use of the forceps in craniotomy, as a protection to the maternal soft parts, and by retracting the vagina (and, if needful, the cervix) enable the operator to use craniotomy instruments safely and expeditiously. It seems to have been lost sight of by the profession, that the primal use of specula were for exactly this purpose; Abulcasis[1] so using them as early as the twelfth century.

In using the forceps after the manner referred to in the title, when the destruction of the fœtus is clearly and fully indicated, a pair of forceps, as wide in the blades as the diameters of the pelvis will permit, are applied in the ordinary manner, and used for fixation and compression of the head, while the vault is perforated and broken or folded up. If preferred by the operator, the blades may be separated to their respective sides of the pelvis, and held by assistants, recrossing and locking them when necessary to make traction and compression.

Writers on obstetrics report cases[2] in which the head was perforated, after ineffectual tractions had been made with the forceps, without removing the instrument, and the delivery subsequently accomplished safely. The use of the forceps in all these cases was, however, accidental—that is, the operator perforated the head, after he had ineffectually used the forceps

[1] Quoted by Schroeder as Abulcasein.

[2] Hodge, Syst. of Obstet., pages 252, 272, etc.

as tractors, allowing them to remain on merely to save time and trouble by their subsequent reapplication. Dr. Rigby, of England, and M. Cazeaux, in France, recommend the forceps as extractors in embryotomy. This article claims the great value of the forceps, when craniotomy is designed, applied *intentionally, prior to perforation*, with the object of affording much greater facility to the operator in his manipulations, and of protecting, almost absolutely, the maternal soft parts from the injuries so common in the hands of even skilful operators, from slipping of instruments, etc. A prominent New York practitioner, who boasts "3000 cases and a year at Vienna," records the slipping of a cephalotribe *eight* times, the operation being finally completed with a blunt hook. Cases are known in which the cervix has been entirely cut away, and in which, in trephining the base of the child's skull, the mother's sacrum has been sawn into. Such injuries would certainly be done away with, if the operator has the vaginal tissues widely dilated by means of the forceps.

To represent the utility of the forceps under such circumstances, we cite the following cases:

CASE I.—M. B., æt. 21; primipara. In this patient the pelvis was of a masculine type, the child's head unusually ossified, and its dimensions large, absolutely and relatively. When Dr. Price saw her, she had been in labor for a long, but indefinite time—as the pregnancy was illegitimate, she had attempted to conceal the fact that she was in labor—and the child was dead. The hand was presenting at the vulvar orifice, which was very much swollen, and the woman's vital forces failing. The hand and arm were returned to the uterine cavity, and the head brought into position. As there was no expulsive effort whatever, the forceps were applied; traction, however, failing to engage the head, considerations involving the safety of the mother demanded prompt removal of the child. Without removing the forceps, craniotomy was quickly performed, after the method described. The mother's soft parts were entirely uninjured, and the woman made a prompt and satisfactory recovery. It seems scarcely necessary to state that version was not performed or attempted in this case, because it was believed that the safety of the mother would be greatly compromised by turning and dragging through contracted and inflamed tissues a large, *still* child.

CASE II.—Mrs. D., æt. 28; second labor. The first labor, two years previously, had been a protracted forceps delivery. The present labor was seen in consultation; it was a summit presentation, and various forceps had been already unsuccessfully applied. A further attempt by Dr. Price was equally unsuccessful in engaging the head, its diameters being at least an inch greater than those of the pelvic outlet. The forceps being *in situ*, a large male fœtus was removed after perforating and crushing the head. The patient's recovery was all that could be desired, and she has since borne a normal child, the labor being easy.

CASE III.—A. G., æt. 22; primipara. Extreme angular curvature of the spine, and the pelvis was narrowed in the conjugate diameter to nearly two and a half inches. The head presented; the occiput was situated posteriorly and unengaged. Dr. Faught applied the forceps (Davis's), but was unable to move the head. Drs. Hampton and Price were called in consultation, and craniotomy was decided upon. At the suggestion of Dr. Price, the forceps (Hodge's) were first applied, the blades being separated to their respective sides of the pelves, and used as a speculum during the subsequent operative procedure. Except for a slight tear of the perineum made during the delivery of the shoulders, this was happily accomplished. The child was a male, and above the average size. The patient's recovery was uninterrupted and satisfactory.

MEDICAL PROGRESS.

REACTIONS OF ALBUMEN.—In a paper recently presented to the Academie de Médécine, M. E. Grimaux showed that solutions of amido-benzoic colloid acquire, by the addition of a small quantity of salt, the property of coagulating under the influence of heat, and he has determined that this phenomenon of coagulation depends both on the proportion of the coagulating agent and on the dilution of the liquid. The study of the reactions of thin solutions of albumen, shows that they become coagulable under the same conditions as the amido-benzoic colloid.

If to dilute solutions of albumen are added small quantities of salts, sodium chloride, sulphate of lime, sulphate of magnesia, hydrochlorate of ammonium, etc., they become coagulable by the action of heat. By the dilution of the albumen, as in the solutions of amido-benzoic colloid, the quantity of water added counteracts the coagulating influence of the salts.

Carbonic acid acts in the same manner as the salts. It is sufficient to cause a current of carbonic acid to pass into albumen to cause the liquid to coagulate at a low temperature. The same thing is seen, as already said, with the amido-benzoic colloid solution. This solution, to which a small quantity of sea-salt is added to cause coagulation in the cold, becomes coagulable when it is saturated by a current of carbonic acid. Albumen to which water is added is not modified. If, on the contrary, these solutions are heated, the albumen is modified. If solutions of albumen, containing one to one hundred of dry materials, are heated to 130° F., a few flocculi are seen to separate. The liquid, filtered clean, is not clouded on boiling, and only becomes opalescent. The action of carbonic acid, cold, causes a gelatinous precipitate which is reduced in a current of air. This precipitate disappears when the liquid is placed in a vacuum, above a solution of potash, or when, after having collected and washed it with water charged with carbonic acid, it is suspended in aërated water.

Dilute acetic acid causes a gelatinous precipitate easily soluble in an excess of acid, reappearing on neutralization with an alkali, and also dissolving in an excess of the latter. The addition of phosphate of soda to the solution of albumen, previously warmed, hastens the precipitation by carbonic acid, but not by acetic acid, and the liquid possesses the reactions of solutions of casein. Albumen, therefore, modified by the action of heat, becomes coagulable by heat when small quantities

of sea-salt, sulphate of lime, sulphate of magnesia, etc., are added to it.—*L'Abeille Méd.*, June 30, 1884.

Porro Operation.—Dr. Tuzzi performed this operation on June 19, at the Maternity in Milan. The patient was in the ninth month of utero-gestation. The operation has been thus far successful for both mother and child.—*Gazz. degli Ospitali*, July 6, 1884.

Surgical Treatment of Gall-stone.—Mr. Lawson Tait has recently carried out his proposal to crush gall-stones by grasping the duct with the forceps. He crushed the stone with great ease by two strokes of the forceps. It was about the size of a cherry, and, after it was broken, the fragments dispersed, and they have given no trouble at all. Since the operation, only a very small quantity of mucous fluid, faintly tinged with bile, has come through the fistula, and the patient's motions are now quite normal in color. He intends to close the fistula in a few days.—*British Med. Journ.*, July 12, 1884.

M. Pasteur's Hydrophobia Experiments.—The experiments which M. Pasteur is reported thus far to have made are said to be an unbroken success. Fifty-seven dogs have been the subjects of investigation. Of these, nineteen were rabid, and by these thirty-eight healthy animals were bitten under uniform conditions. Of the thirty-eight, one-half the number had been previously inoculated, or "vaccinated," with attenuated virus; the other half had not. The latter, without a single exception, died with unequivocal signs of rabies, whereas the nineteen others remain as well as ever. They will be watched for a year by veterinary surgeons to see whether the inoculation holds good permanently or only temporarily. If rabies be not spontaneous in its origin, and if the experiments of Pasteur all turn out successful, there seems no reason why canine madness should not be extirpated from our midst.—*Lancet*, July 12, 1884.

Chromic Acid as a Cauterant in Diseases of the Nose, Pharynx, and Larynx.—In a recent communication on this subject to the Société française d'Otologie et de Laryngologie, Dr. Hering refers first to the fact that chromic acid acts on albumen very much in the same manner as does nitric acid; it coagulates it, and also the mucous secretions; the saliva, and the gelatinous tissue of the bones. This explains the action of chromic acid on the pituitary membrane. Being used for preserving and hardening anatomical specimens whose form and structure it is desirable to maintain, it may be considered as an antiseptic. It arrests putrefaction in blood, muscles, and the urine. According to Dugal, its effect on the infusoria is greater than that of carbolic acid. It has been given internally by Bonnefont, Vincent, and Heyfelder, only in cases of inveterate syphilis, and Güntz has recently published a new method of treating syphilis by excluding mercury and administering chromic acid water.

It is well known that workers in chromic acid frequently have marked effects from its action on the nose, pharynx, and respiratory organs. A peculiar form of rhinitis is developed, the last effect of which is the destruction of the nasal septum and perforation of the cartilages. Curiously enough, Delpech-Hillairet states that snuff-takers are exempt from these effects. When applied to the healthy skin the acid only causes a yellow tint; but with the slightest excoriation pain and caustic effects follow.

To cauterize any particular spot, a small piece of charpie, covered with chromic acid, is placed on it. In a few seconds the charpie is transformed into a blackish mass, and at the same time there is some production of heat. The charpie then acts on the tissues in the same manner as the thermo-cautery, forming an eschar, the elimination of which, proceeding from the periphery to the centre, commences in from five to eight days. The falling of the eschar leaves a suppurating wound. Concentrated aqueous solutions, of one-half or one-third, do not cause pain when applied to condylomata. These simply retract and fall off without hemorrhage. The application being repeated, they disappear entirely, and leave a small ulcer, which readily heals.

When applied in a pure form, chromic acid is a powerful corrosive agent. As a corrosive, it is used for removing condylomata, papillomata, warts, lupus, carcinomata, and malignant ulcers. It may also prove useful in removing telangiectases and indurations of the cervix uteri. There are two principal objections to its general use in affections of the nasal mucous membrane. First, the inconvenience as to the quantity and the operative procedure, and, second, the fear of chromic acid poisoning. But these are due to the methods in ordinary use, and not to the remedy. Hering advises the following: Over an ordinary lamp one heats a small crystal of the acid on the end of a silver probe. When heated cautiously this crystal loses its water, and forms a viscid, thick mass, which soon hardens on the end of the probe. If the heat acts for too long a time, or too suddenly, the surface of the crystal is transformed into a green layer, friable and porous, and having no corrosive action. This method enables the operator to judge of the time for the application and the amount of pressure to be used in cauterizing a part. A glass rod may be used instead of a silver probe, or a piece of platinum or iron wire may be used. By this method very simple instruments are required. The operator touches lightly, and several times, the surface to be acted upon, and soon sees a small spot streaked with yellow, which gradually enlarges and becomes an eschar. To get a less cauterant effect, it is sufficient to plunge a glass rod into the brownish deposit at the bottom of a chromic acid bottle. This deposit is very aqueous, and less active than the burnt crystal.

When the chromic acid cautery is applied to the buccal and pharyngeal mucous membrane, only very slight pain is produced. Hering has never had a case of chromic acid poisoning after even frequently repeated cauterizations. He always follows them up with a washing of pure water, which is continued as long as the water comes away with a yellowish tint. When there is any danger of some of the chromic acid getting into the stomach he gives the patient a weak solution of bicarbonate of soda. When the cautery is applied to the larynx the patient should be made to cough and expectorate immediately after the operation.

Hering states that of all the means thus far used by him in the treatment of nasal catarrh, he has not found one which is equal to chromic acid in rapid and energetic action, especially in cases of thickening of

the mucous membrane accompanied by obstruction and an abundant muco-purulent secretion, *without excessive redness of the mucous membrane*. The nose should be first washed out with a weak, tepid solution, and then the chromic acid applied to the tumefied parts on one side only. After this water is quickly thrown in. If the first cauterization does not produce the desired effect, the yellow eschar should be removed with the pincers, and a second application made, or several applications may be necessary.

In cases of adenoid hypertrophies Hering has had the best results with chromic acid. He has also been successful in destroying the pedicles of polypi, and in treating pharyngitis granulosa and pharyngitis hypertrophica lateralis, and hypertrophy of the tonsils. Care must be used in the last case when there is a cavity in the gland, lest a portion of the cauterant remain in the cavity. This treatment is not applicable to indurated hypertrophy of the tonsils. He has used the acid in the larynx, with success, in cauterizing the seat of two mucous polypi of the chords, which had been removed by Störk's forceps; also in cases of laryngeal ulcerations and in ulcerations of the chords, whether tubercular or syphilitic. The application causes scarcely any pain, and stops the cough. In all cases the acid must be applied with great care.—*Rev. Mens. de Laryngol. d' Otol. et de Rhinol.*, May and June, 1884.

LAPAROTOMY FOR VOLVULUS.—This operation was performed at the Ospitale Maggiore, in Bologna, on April 19, by DR. MEDINI. The patient was doing well on June 11.—*Gazz. degli Ospitali*, June 11, 1884.

CHANCROUS LYMPHATIC ABSCESSES.—Lymphatic abscesses, says DR. VERDIER, are a rare, but still possible complication of simple chancre. It is difficult to determine precisely the etiological conditions which are involved in their formation. From a pathogenic point of view, they are the result either of the introduction of the chancrous poison into the lymphatics, or of an intense lymphangitis which succeeds the irritation caused by the chancrous ulceration. Inoculation establishes the diagnosis between the two forms: positive in the first case, and negative in the second.

In all probability suppuration occurs at the interior or in the walls of the lymphatic vessels. The ulceration resulting from the spontaneous or surgical opening of these abscesses rapidly takes on the form of chancrous ulceration.

As regards the treatment, it differs but little from that of the simple chancre. Cauterizations give excellent results. In most cases nitrate of silver will suffice. For topical dressings, iodoform, aromatic wine, and calomel and pyrogallic acid pomades are very useful.—*Revue de Thérap.*, June 15, 1884.

ABSCESS OF COWPER'S GLANDS.—M. VERNEUIL reports the case of a man, æt. 62 years, who came under his care at La Pitié. For some time he had had symptoms of dysuria. These finally became very pronounced; urination became extremely painful, and the desire frequent. Examination showed a stricture of the membranous portion of the urethra.

M. Verneuil diagnosticated stricture of the urethra, and ordered a bath and a purgative, and next day passed a No. 3 bougie, the size being then changed every two days, until a No. 9 was passed. This was soon followed by an attack of orchitis, and this by an exudation into the tunica vaginalis, which afterwards became encysted. Dilatation of the urethra was kept up, and the patient left the hospital able to pass a No. 15. He returned in about three weeks, with a large swelling of the right side of the scrotum; this was due to abscess formation, which opened in five days. Three days afterwards the patient died.

The autopsy showed the bladder small and retracted, and its walls thickened. A No. 7 sound could be passed *per urethram*. Near the prostate a small quantity of pus was found. On dissection, a small cavity was found, filled with phlegmonous, greenish pus. It was situated at the posterior part of the urethra, related anteriorly with the membranous portion of the urethra, and behind with the bulb of the urethra and the perineal muscles, above with the prostate, and below with the bulb. In the opinion of Verneuil and Cornil, this was a case of abscess of Cowper's glands.—*Progrès Méd.*, June 14, 1884.

WATER AS A DIURETIC.—In an article on the action and use of diuretics, in the *Practitioner*, May, 1884, DR. T. LAUDER BRUNTON says that water is, perhaps, the most powerful diuretic we possess, although fewer experiments have been made with it upon animals than with the others. The diuretic action of water drunk by a healthy man is very marked, and it appears impossible to explain its elimination by a mere increase in blood-pressure, whether general or local. It has the power of increasing tissue-change, and thus multiplying the products of tissue-waste which result from it, but it removes these waste products as fast as they are formed, and thus, by giving rise to increased appetite, provides fresh nutriment for the tissues, and thus acts as a true tonic. In persons who are accustomed to take too little water, the products of tissue-waste may be formed faster than they are removed, and thus accumulating may give rise to disease. If water be freely drunk by such persons, the product of waste will be removed, and health maintained or restored. Many gouty persons are accustomed to take little or no water except in the form of a small cup of tea or coffee daily, besides what they get in the form of wine or beer. In such people a large tumbler of water drunk every morning, and especially with the addition of some nitrate or carbonate of potassium, will prevent a gouty paroxysm. Still more numerous, possibly, is the class of people who arise in the morning feeling weak and languid, more tired, indeed, than when they went to bed. Many such people are well fed, they sleep soundly, and it seems almost impossible to believe that the fatigue which they feel in the morning can result from imperfect nutrition, more especially as one finds that after moving about, the languor appears in a great measure to pass off. It seems that this languor must depend upon imperfect removal of the waste products from the body, as we know that the secretion of urine in healthy persons is generally much less during the night than during the day. Such people should drink a tumbler of water before going to bed in order to aid the secretion of urine and of the waste products during the night. In some cases, though not in all, the result has been satisfactory, and possibly

might have been still more so, if the bicarbonate and nitrate of potassium, which are so useful in cases of gout, had been added to the water.

Lately a plan of treating gout by draughts of water at intervals during the day has been a good deal employed, and is in many cases successful. The following is the diet used along with this treatment by a medical friend:

7.30 A.M. Ten fluidounces of very hot water. 8 A.M. Breakfast: equal parts of weak tea and milk, a small quantity of white sugar, a slice of fat bacon without a strip of lean, bread, and fresh butter. 1 P.M. Milk-pudding, rice, sago, tapioca, macaroni, or blanc mange, and small biscuits with butter, ten fluidounces of hot water. 4 to 5 P.M. Ten fluidounces of hot water. 6 P.M. Dinner: white fish or fowl (usually boiled), greens, bread, no potatoes, claret seven fluidounces. 8 to 9 P.M. Ten fluidounces of hot water. 11 P.M. Ten fluidounces of hot water.

If he indulges either in meat or game, or drinks copiously of claret, or omits one or two glasses of hot water, he feels gouty and gravelly next day. It is obvious that by this plan of treatment, in which the ingestion of nitrogenous food is most strictly limited, at the same time that every facility is given for the elimination of the products of nitrogenous waste by the large quantities of hot water drunk in the course of the day, the accumulation of waste in the tissues ought to be most effectually prevented.

The Therapeutics of Puerperal Rupture of the Uterus.—Dr. T. Kroner gives a table of 47 cases of rupture of the uterus, 19 being complicated, 10 uncomplicated, and 18 doubtful cases, all the cases having occurred during and since the year 1873. Of the complicated cases, 11 died—3 in twenty-four hours, 1 in thirty hours, 1 in twenty-one hours, 1 in thirteen hours, 1 in eight hours, 1 in a "short time," 1 in three days, 1 in five days, and 1 in seven days. Of the uncomplicated cases, 5 died—1 "soon," 1 in six hours, 1 on the next day, 1 in three days, 1 during labor. Of the 18 doubtful cases (doubtful as regards peritoneal complications), 9 died—1 in twenty-four hours, 1 in twenty-two hours, 1 in two hours, 1 in twelve hours, 1 in an hour and a half, 1 in forty hours, 1 in half an hour, 1 in three days, and 1 time not stated. In the whole number of cases only one primipara is mentioned, although in some of the cases no mention is made of the number of labors. Of the cases in which this is mentioned, rupture occurred 4 times in 2-paræ, 3 times in 3-paræ, 8 times in 4-paræ, 3 times in 5-paræ, 3 times in 6-paræ, 2 times in 7-paræ, 1 time in an 8-paræ, 3 times in 9-paræ, 1 time in a multipara. Rupture occurred 3 times in one patient, with recovery. Rupture followed the administration of ergot in 2 cases.

Of the whole number of cases, therefore, there were 25 deaths, and 22 recoveries. The fact that there were so many recoveries makes the tables especially interesting. Of these, 8 were cases of perforating rupture, with partial or total extrusion of the fœtus into the abdominal cavity. The shortest time of recovery without drainage was eighteen days; with drainage, fourteen days; the longest without drainage was seven weeks; with drainage, nine weeks. It would seem that good natural drainage, by a compress around the abdomen, is all that is necessary.

Besides the cases tabulated, Kroner reports a personal case—3-para, rachitic—in which rupture took place one hour after the rupture of the membranes. The child was delivered dead. The placenta slipped into the abdominal cavity, between the anterior uterine wall and the abdominal wall, and was removed with the hand. The uterus was washed out with warm carbolized water. The after-treatment consisted in the administration of opium, ice-bags over the abdomen, warm fomentations, and mild laxatives. The patient had diffuse parametritis, and an attack of remittent fever. The temperature became permanently normal in five weeks, and the patient was well in seven.

In none of the cases was the abdominal cavity opened. The usual treatment was, in the main, that used by Kroner in his successful case, local bloodletting being also used in some cases.—*Centralbl. für Gynäk.*, June 14, 1884.

External Œsophagotomy.—At a meeting of the Moscow Surgical Society, Dr. A. S. Knie (*Letopsis Khirurgitches Obshtchest.*, No. 8, 1884) related the case of a man aged twenty-two, who swallowed a piece of bone during a hasty dinner, and in whom, eight days later, œsophagotomy was successfully performed after all other attempts at dislodging or extracting the foreign body had utterly failed. The swallowing of solid food became impossible; that of fluids painful. The patient considerably lost flesh and grew weak from insufficient nutrition, sleeplessness, and fever, and began to expectorate a fetid purulent discharge, stained with blood. A sound detected that the foreign body was impacted at the level of the manubrium sterni. On the ninth day Dr. Knie, assisted by Drs. A. Belaieff and W. Schkott, made an incision along the internal edge of the left sterno-cleido-mastoid muscle, from the cricoid cartilage down to the sternum, and found his way to the œsophagus between the cervical vessels and the larynx. While the operators were examining the gullet with the fingers, fetid pus and mucus began to escape from the wound, thus clearly showing that a perforation already existed. The hole being enlarged, the foreign body was (with considerable difficulty) extracted by means of forceps. It proved to be a piece of bone 3 by 2 centimetres, with four very sharp angles, and rough surfaces. Under antiseptic after-treatment, the œsophageal fistula closed on the fifteenth day, and the patient was discharged cured four weeks after the operation. After an able general discussion of cases of foreign bodies in the gullet, the author strongly insists on the necessity of energetic treatment. Touching the results from external œsophagotomy for foreign bodies, Dr. Knie estimates the recoveries at about eighty per cent.—namely, of thirty-three cases collected by König in *Deutsche Chir.*, Fasc. 15, p. 120, twenty-six were successful; to these the author adds his case and two successful cases of Monastyrsky, in the *Vratch*, No. 6, 1882.—*London Medical Record*, June, 1884.

Tracheotomy in Children Under Two Years of Age.—This is the subject of a recent inaugural dissertation by Gustav Chaym. Trousseau took the position

that in children under two years of age tracheotomy for diphtheria was contraindicated on account of the undesirable consequences.

At Prof. Küster's suggestion, Chaym collected material on this subject—almost one thousand cases. As regards the mortality, there were fifty-six cases of tracheotomy in children one year old; eighty-four per cent. died, and of nine hundred and twenty-one of two years of age, eighty-five per cent. died, while the average mortality of tracheotomy for diphtheria fell to between sixty-seven and seventy-five per cent. As to the mooted question whether the operation gives better results in hospital or private practice—it seems that they were better in the latter. The causes militating against the success of the operation in these young subjects are, the slight power of resistance of very young children, the occurrence of dentition, the disposition to reflex cramps, the difficulty of properly nourishing them, the extreme mobility of the trachea, the weakness and narrowness of the air-passages, and the consequent dangers of wounding the œsophagus and other important anatomical structures.

Howard Marsh states that tracheotomy on a young child with a short and fat neck is a most difficult and tedious operation. For the *technique* of the operation, Chaym recommends the high operation, which, by Bose's oblique section of Hüter's thyro-laryngeal fascia, gives room enough, and also advises section of the cricoid cartilage. A canula of 4 mm. is also recommended. The after-treatment must be conducted with the greatest care. For troubles of deglutition the temporary tamponade is recommended, the best being the glycerine-wadding above the canula, as used by Israel. —*Deutsche med. Wochenschr.*, July 3, 1884.

THE CARRIERS OF INFECTION IN PUERPERAL FEVER. —LOMER read a paper on this subject before the Gesellschaft für Geburtshilfe und Gynäkologie, on March 28, 1884. Pathologico-anatomical researches show these to be chain-forming, round, and non-moving microorganisms, in the diphtheritic layers of the uterine mucous membrane, in the uterine tissue, the peritoneal exudation, the lymph-spaces of the diaphragm up to the pleural cavity, in the kidneys, and in every other organ.

In two puerperal fever patients, Lomer found them once in pemphigus vesicles in large number fourteen days before death, in the other case four days before death, in the blood. After death they were found in all the organs.

The culture-experiments of Dr. Franovik, not yet concluded, show that the pure cultures differ both from the micrococci of diphtheria found by Löffler, and from the erysipelas-cocci found by Fehleisen. The inoculations of pure cultures made by Fränkel and Doléris have not, up to the present time, given constant and agreeing results.

Besides the chain-forming micrococci, other microorganisms were found in puerperal fever, which seemed to indicate mixed infection. Clinically, however, these cases did not differ from the others in which only the chain-like micrococci were found. Lomer further reports three cases of puerperal fever, in which the micrococci were not found even after the most careful search made in the Royal Health Office.—*Deutsche med. Wochenschr.*, July 3, 1884.

EXTIRPATION OF THE KIDNEY.—At the meeting of the Medico-Chirurgical Society of Glasgow, on March 7, 1884, DR. MACEWEN showed a patient from whom the right kidney had been extirpated. The patient was admitted into the wards in an emaciated, semi-delirious condition, with high temperature and weak pulse. The history available at the time was of the most meagre description, and to the effect that he had been troubled with a urinary affection for about a year previously. His urine was loaded with pus. On examination, microscopically, a few tube-casts containing pus-corpuscles were seen, along with numerous crystals of phosphate of lime. There were dulness and swelling in the right renal region, which was painful on deep pressure. The diagnosis was renal calculi with abscess of the kidney.

Within the first twenty-four hours of his admission into the hospital, it was evident that he was sinking, and that something would require to be done at once for his relief. It was thought that the renal calculus might be removed while the abscess could be opened and drained. The renal calculi were removed; one from the pelvis of the kidney of irregular form, one of its projections situated in the ureter; the other from the substance of the gland. The kidney was found to be riddled with abscesses, and as it was apparent that it could no longer perform its secretory functions, it was removed. The patient recovered from the operation with remarkable rapidity.

DR. GAIRDNER said that the course of events in these cases was something like this. Along the ordinary channel pus was discharged for a considerable period for a greater or less period, this going on interminably. If the patient does not succumb, then there came a time when the kidney was structurally and functionally destoyed. If an opening were now made externally, pus was discharged in this way, and this might go on indefinitely. The next step was that of waxy degeneration, or Bright's disease. It was perfectly clear that, if they were satisfied that the kidney was permanently disabled, they might save the patient's life by having recourse to the operation for its removal.—*Glasgow Med. Journ.*, July, 1884.

THE ANTI-EPILEPTIC ACTION OF BROMIDE OF POTASSIUM.—In the *Neurologisches Centralblatt*, No. 2, 1884, DR. P. ROSENBACH has an article on this subject. Bromide of potassium administered to animals decreases the excitability of the cerebrum, so that stronger currents are necessary in order to call out, through irritation of the motor centres, the minimal disturbances of the corresponding muscle groups. This has already been ascertained by Albertoni. Rosenbach now concludes that the cerebral cortex is the point of origin of epilepsy and of epileptic attacks, and has undertaken to determine upon what part of the cerebral mass bromide of potassium acts more particularly. With this view he irritated the motor region of the uninjured gray matter, and after destruction of the same, both before and after using the drug. From this it was determined that on sufficient intoxication with bromide of potassium (in dogs) the excitability of the cerebral cortex diminished, or entirely disappeared, whilst the excitability of the underlying substance remained almost unchanged.—*Deutsche med. Wochenschr.*, July 3, 1884.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, AUGUST 2, 1884.

CHOLERA DISINFECTION.

WE have given briefly in these columns the means to be employed to prevent the introduction of cholera into the United States, and we now invite the attention of our readers to the best means of combating the disease should it once obtain a foothold here. It is understood, from what has already been said, that municipal cleanliness is absolutely necessary to prevent the germs of the disease from multiplying outside the human body, and the only question with which we have now to deal is, What is the best plan that can be adopted to destroy the germs as they pass from the cholera-infected person?

Cholera is not transmitted by contact, but by an organic infecting matter, passed with the evacuations of those affected, which must gain entrance into the intestinal canal to produce cholera in another. In this lies the whole secret of an effectual preventive treatment, if we can destroy the organic infecting matter the instant it has passed from the patient, cholera cannot spread; or, what amounts to the same thing, if we can prevent the infecting matter of the cholera dejecta from reaching the intestines of other persons, we prevent them from getting cholera. Our efforts in this direction, therefore, constitute the true preventive treatment of this disease. If we can only preserve the drinking water from contamination, it is impossible for cholera to become epidemic. The leading principles upon which we must rely for effecting this object are, first, to destroy the organic infecting matter as it passes away from the patient by means of a solution of corrosive sublimate, or of sulphate of iron, or by some acid reagent, taking care that the evacuations thus treated are buried in the earth away from wells or sources of water supply; and secondly, to disinfect or destroy all articles of clothing, furniture, or, in fact, anything to which the choleraic discharges could adhere.

The popular idea of a disinfectant is a something which will destroy a "bad smell," while the fact is, such destruction may not affect the fomites of cholera, which are almost odorless. A cholera disinfectant must be a germicide, or it is worthless.

The simplest and cheapest disinfectant for this purpose is a solution of bichloride of mercury or a saturated solution of sulphate of iron (copperas). A solution of bichloride of mercury is readily made by adding an equal quantity of common salt as a solvent, and dissolving in water in the proportion of 1 gramme of the mixture to 1000 cubic centimetres of water, or 1 ounce to 8 gallons of water; and a saturated solution of copperas by dissolving all the powdered copperas a given quantity of water will take up. Both of these disinfectants are entirely odorless, and the former colorless.

A small quantity of either of these solutions should be placed in the vessel receiving the discharges from a cholera patient, and another portion poured over them immediately after the vessel is used. Then the contents of the vessel should be emptied into the water-closet, buried, or, better still, thrown into a furnace. All clothes or other domestic articles that can be washed which have been contaminated, should be soaked in a solution of one or the other of these disinfectants, and if the furniture or floor has received any of the fomites, it too should be thoroughly washed with the bichloride solution. These solutions can be used about the premises, if necessary, with a sprinkling-pot, and all suspicious places wet down and thoroughly disinfected.

There are many other cheap disinfectants, but they are open to the objection of disagreeable vapors, such as chloride of lime, carbolic acid, sulphurous acid, etc. The bichloride solution, besides being odorless, is no more dangerous than any other disinfectant that can be named, while it is more cleanly and quite as readily prepared, as well as being cheaper than the now favored carbolic acid.

Isolated hospitals for cholera patients who are unable to provide for themselves, and their immediate removal to these hospitals upon the appearance of the first symptom—the *malaise* which usually precedes cholera—would simplify the management of the disease, and with absolute cleanliness, proper disinfection, a well-regulated diet, and unpolluted water, all fear of an *epidemic* of cholera in the United States may be dismissed, even should it escape our quarantine guards and appear in our midst.

ANTIPYRIN · THE NEWEST ANTIPYRETIC.

The search for a substitute for quinine, although not successful in the main object thus far, has been fruitful in the discovery of new remedies. Amongst these may be mentioned, resorcin, quinoline, pyrocatechin, hydroquinone, and kairin. All of these are synthetical products. The last mentioned of this group, kairin, has proved remarkably effective as an antipyretic. All of them have been successful in varying degrees as antiseptic and antipyretic remedies, but they do not reach the peculiar eminence hitherto attained by quinine only. But this partial success has greatly stimulated the productive activity of chemists engaged in these researches, and their efforts have been rewarded by the discovery of antipyrin. This very appropriate designation is applied to an artificial alkaloid produced synthetically by Dr. L. Knorr, of Erlangen, by the action of acetic ether on aniline. It is also obtained by oxidation from quinoline or chinoline, one of the antiseptics mentioned above. It has been patented by Dr. Knorr, for whom it is manufactured by Messrs. Meister, Lucius, and Brünnig, industrial chemists.

Antipyrin occurs in the form of a white crystalline powder, having a slight aromatic odor, and a somewhat bitter taste, which may be effectively disguised by solution in some medicated water or in wine. It is readily soluble in water, in the proportion of one to three. The dose for an adult as an antipyretic is from 15 to 30 grains, given at intervals of an hour, until 75 or 90 grains have been taken. This quantity can be administered without causing inconvenience except, in rare instances, vomiting, according to Dr. Ferdinand May, who has experimented with it in the Municipal Hospital of Cologne, and publishes his results in the *Deutsche med. Wochenschrift*, No. 24, 1884. In the same issue of this journal we find a paper by Dr. C. Rank, of Stuttgart, on the use of antipyrin in febrile affections, employed chiefly by the hypodermatic method. Its ready solubility, and the absence of any resulting important local injury, render it especially available for this mode of administration.

The first investigations of the physiological action of antipyrin on animals and on man, were made by Filehne, and appeared in the *Zeitschrift für klin. Med.*, Band vii., Heft 6. The papers quoted above have followed. Besides these, a short note on some clinical experiences with the new remedy appears from Dr. Paul Guttmann in the *Berliner klin. Wochenschrift* for 19th of May, last. From these sources, we lay before our readers, a succinct account of the action and uses of a remedy which appears to be, from the present state of opinion, the nearest approximation to a substitute for quinine hitherto discovered.

The effect for which it has thus far been employed is the antipyretic, and in various acute and chronic febrile affections. The influence on the temperature of fever has been constant, although not to the same degree in all individuals. The maximum depression of temperature is attained in from three to five hours after the commencement of the treatment. The effect is maintained for from seven to nine hours, and in some instances is prolonged to twenty hours. The pulse decreases in frequency as the temperature declines, but the two functions do not maintain an absolute ratio, and the respiration is not affected. Children and weak adults are more readily influenced by it, and therefore require less of the medicament to produce a given result.

Rank embodies in some formulated conclusions the results of his observations. He finds that antipyrin is an antipyretic of the first importance in all the acute febrile affections: that by subcutaneous injection the effects are produced more decidedly and more promptly than by the stomachal administration, and that a less quantity of the remedy suffices, thirty grains being equal in power to twice that quantity given by the mouth; that a concentrated solution, 15 grains in 8 minims of water, can be employed by the hypodermatic method, without any local injury or accident, and that about twice the quantity of antipyrin produces the effects of a given quantity of quinine, for which it appears to be an efficient substitute.

The charts which illustrate May's articles exhibit, in the clearest manner, the constant influence of antipyrin on the temperature and pulse. As compared with kairin, it presents an important advantage which Guttmann has emphasized: the rise of temperature which comes on after the depression is not so abrupt, nor is it preceded by a chill, the maximum heat being attained in about the time occupied in reaching the minimum produced by the administration of the remedy. Although it is conceded by the observers quoted that whilst the pulse and temperature maintain a certain regular ratio, the respiration is not affected. One of the observations given by May is opposed to this view, for after forty-five grains of antipyrin the number of the respiratory movements fell from 30 per minute to 18, in the same ratio as the decline in the pulse and temperature. Further investigation is needed to decide this point.

Kairin and quinine are the agents with which antipyrin is to be compared. Guttmann, who makes some observations on the comparative antipyretic action of these three remedies, concludes that antipyrin is superior to kairin, but that in corresponding quantity quinine is more effective than antipyrin. Thus far we have had no observations on the use of the new remedy in malarial fevers, which will be the *experimentum crucis*, as regards its curative powers. There can be no advantage in the administration of

antipyrin, as respects price, at the present time. A large demand will, of course, lessen the expense of production, but as a monopoly will exist in the person of the holder of the patent, the price can be artificially maintained.

In concluding, we cannot withhold the expression of our conviction, that an American physician would not have patented such a beneficent discovery. We are sure, had he done so, that he would experience the reprobation of the whole profession, a fact which shows that if we may not possess the scientific training of our German colleagues, we are more mindful of certain ethical principles.

DRAINAGE OF CEREBRAL ABSCESS.

In a timely article contributed to the *American Journal of the Medical Sciences* for July, Dr. Fenger and Dr. Lee, of Chicago, record a most interesting case of abscess of the brain the result of shot wound, which terminated in recovery after trephining, draining, and washing out the cavity with antiseptic solutions. The result affords a capital illustration of the fact, which few surgeons of the present day will deny, that a cerebral abscess should be treated upon the same principles as an abscess of any other organ or region.

One of the great difficulties in the treatment of cerebral abscess consists in locating the precise seat of the lesion. Not a few cases have been reported in which, after the skull had been opened, the knife or trocar missed the abscess, and the patient died unrelieved. This embarrassment may be obviated by multiple exploratory aspirations, conducted with a syringe, provided with a needle four inches long, with a rounded instead of a cutting point, through which division of small bloodvessels is obviated. The procedure, which was originally practised by Renz, in 1867, was adopted in the case under consideration, and the needle served as a guide, along which a pair of forceps was passed for the evacuation of the pus.

It would appear from this paper, as well as from one published by Dr. Amidon in The Medical News for June 21st, that up to the present time only three cases of cerebral abscess have been treated by drainage. In that of Burchard, the tube was inserted along the track of the projectile; in that of Fluhrer, also one of pistol-ball wound, the projectile was extracted through a counter-opening, and a tube passed through and through; while in the case of Fenger and Lee the drain was carried into the cavity of the abscess through the track made by the forceps to evacuate it.

That drainage should in similar cases be practised on general principles, is attested by the remarkable fact that the three cases in which it was resorted to recovered. The truth of the matter is that the sooner we learn to regard a cerebral abscess in the same light as an abscess elsewhere, the better it will be for our patients. To tap and drain a collection of pus in the brain is not a bold or hazardous procedure; the danger consists in letting Nature pursue an unaided course; and in the present state of our knowledge of the advantages of antiseptic surgery, the practitioner will be deemed bold indeed, who idly waits for "spontaneous resolution."

ANTISEPTIC OBSTETRICS.

The subject of antiseptic obstetrics has attracted so much attention lately that our readers will be glad to know the methods adopted, and the results obtained in the famous Rotunda Hospital of Dublin. The Master, Dr. Macan, in his last annual report states that during the year ending November, 1883, 1090 women were delivered, and only 6 died; the mortality was, therefore, 0.55 per cent., or 1 patient in 181.6. The usual mortality in childbed, as estimated by both the late Dr. McClintock and Dr. Matthews Duncan, is 1 in 120 in private practice.

For the prevention of septic infection, the students and nurses are required, before examining a case of labor, to wash their hands in a 1 to 40 solution of carbolic acid, and carefully use a nail-brush, afterward dipping them in a 1 to 1000 corrosive sublimate solution. Further, in order to lessen the frequency of vaginal examinations, the students are taught to palpate the abdomen, and thus to recognize not only the presentation, but also the exact position of the child's head, back, and limbs.

As soon as the child is born, the patient is turned upon her back to prevent the entrance of air into the uterus, and her genitals are never touched after delivery except in case of hemorrhage, ruptured perineum, or retained placenta. Before stitching a ruptured perineum, the vagina is washed out with the 1 to 40 carbolic acid solution; and if the hand is introduced into the uterus, the uterine cavity is similarly washed out, or with a 1 to 2000 corrosive sublimate solution.

The vagina and external genitals are carefully washed before every operation, and the uterus syringed out afterward, and a pessary containing one drachm and a half of iodoform passed to the fundus, and left there.

The tubes used for vaginal or uterine injections are of glass, one for each bed, and they are kept in carbolized water. To prevent the entrance of air, which may be immediately, or remotely dangerous, the old India-rubber siphon syringes have been replaced by irrigators which act by gravity. Gum-elastic catheters have been banished, and only silver instruments are used.

Dr. Macan holds that if the prophylactic precau-

tions taken during labor are sufficient, there can be no necessity for any prophylactic antiseptic injections, whether vaginal or uterine, in the puerperal state, and he never allows them to be used either in hospital or in private practice. The external genitals are not even washed with antiseptic solutions, but with warm water, a piece of oakum instead of a sponge being employed. No antiseptics are used on the napkins applied to the external genitals.

The very low mortality observed in the Rotunda under this method of treatment is strong testimony in its favor. Nevertheless, we do not believe the question of childbed mortality can be settled by one year's experience in a single hospital, for just as there are practitioners who claim to have attended five hundred, or even one thousand labors without seeing one case of puerperal septicæmia, so there are years when the mortality of maternities may be very slight. A question like this must be decided by observations continued for a long time, and by inductions based on a large number of cases.

THE TREATMENT OF ABORTION.

Dr. Macan, in the report to which we have just referred, states that during the year 16 cases of abortion were admitted to the hospital. The treatment was expectant as long as possible, and in none was the vagina plugged, but in case of excessive hemorrhage before the cervix was sufficiently dilated to allow removal of the ovum, the cervix was plugged with a tupelo tent, or dilated with Hegar's instrument, and the ovum removed. When any part of the ovum remained, causing putrid absorption or hemorrhage, the uterus was well washed out with the corrosive sublimate solution, the curette used, and then the corrosive sublimate again, and in septic cases, in addition, an iodoform suppository was introduced.

The record of Dr. Macan's practice is a contribution to the subject of the proper management of inevitable abortion, a topic that has attracted much attention in recent years in this country. The profession, in fact, is yet divided in opinion, some advocating immediate and active interference—attacking *vi et armis*, that is with big and little curettes—and emptying the uterus as promptly as possible; while others more conservative, or at least less radical, prefer an expectant course, letting their action depend upon events, persistent or severe hemorrhage, or an offensive discharge, being signals for immediate evacuation of the uterus.

No Cholera or Yellow Fever in the United States.—The reported cases of cholera on the Mississippi River Steamer Annie P. Silver, and of yellow fever at New Orleans, have fortunately both turned out to be false alarms. The first report arose from the statement of a Dr. Pease, at Port Anderson, on the Mississippi River, who claimed that a child belonging to a family direct from Toulon had died on the steamer, and was buried at that place. Steps were immediately taken by Surgeon-General Hamilton to ascertain the facts, when it was definitely settled that the child died of summer complaint, and the family had never been to Toulon, but were from Mexico, and had been in New Orleans for some time before taking passage on the Silver. The yellow fever scare was occasioned by a suspicious death in New Orleans, which a post-mortem examination settled as not yellow fever.

SPECIAL ARTICLE.

THE RATIONAL TREATMENT OF GOUT, URIC ACID GRAVEL, AND ACUTE RHEUMATISM.

It is one of the encouraging facts in connection with the development of our science, that we are certainly acquiring a more accurate knowledge of those metabolic processes, without a correct understanding of which our treatment of the affections known as derangements of nutrition must remain empirical and uncertain. The latest contribution to such knowledge is a brochure by Dr. P. W. Latham, Downing Professor of Medicine at Cambridge, Eng., "On the Formation of Uric Acid in Animals and its Relation to Gout and Gravel."

Rejecting, in common with most modern physiologists, the older view that uric acid is the result of imperfect oxidation of tissues, he ascribes its formation in the human subject partly to defective assimilation, and partly to a "condensation process," in much the same way that cyanuric acid and biuret are condensation products of urea.

In the human subject, glycocine united with cholic acid, is poured into the intestine as glycocholic acid, a constituent of bile. After the bile has served its purpose in digestion, the glycocine and taurine of the taurocholic acid, with the leucin and tyrosin arising from albumen-digestion, are converted by the liver-cells into urea, which is returned to the blood, and reappears in the urine.

The appearance of uric acid in the secretion of one animal, and of urea in another, is the result primarily of the non-conversion of glycocine into urea, whether that glycocine be derived from the bile poured into the duodenum or formed elsewhere in the body. That it is from the bile is probable from the fact that in the carnivora, whose urine contains little or no uric acid, the bile contains only taurocholic acid, and therefore no glycocine.

Now, as to the abnormal formation of uric acid in the human economy. Just as in diabetes the liver or some other part is unable to effect the metabolism of the glucose, which then passes into the circulation and is discharged by the kidneys, so in gout or gravel the imperfect conversion of glycocine is the primary and essential defect. It passes from the intestine or

elsewhere into the liver, through whose agency it is united with the urea resulting from the metabolism of leucin and tyrosin, and is converted into hydantoin, which passes into the blood and thence to the kidneys to be combined with another molecule of urea, forming ammonium urate, a portion of which overflows into the circulation and is converted into sodium urate.

Thus can be explained the effects of the sluggish liver in certain free eaters and drinkers. But as not every toper and gourmand develops gout, and every gouty person is not necessarily a toper or gourmand, Dr. Latham suggests that we look further, say to the nervous system—the medulla or spinal cord, or both—for some etiological change, which may be either hereditary or acquired. This may be primary in the nervous system, affecting the digestive apparatus through the vagus if in the medulla; or affecting the joints, through the spinal nerves if in the cord. Or it may be primary in the liver, and the accumulated uric acid in the blood affect the medulla and cord secondarily, and in turn produce nutritive changes, or inflammation in the joints connected with that part of the cord.

Important corollaries are deducible from these facts as to why gout does not generally appear until after middle life, and as to its association with chronic lead-poisoning, both of which furnish a kidney more or less crippled, which in its sound condition could have thrown off the uric acid. So, too, the phenomena of rheumatism may be similarly explained, supposing the lactic acid poison to result from a like defective metabolism, while the curative action of salicylic acid may be due to its combining with the antecedent of lactic acid, thus stopping its formation. This view is supported by the fact that mental or muscular fatigue, worry, or excitement will often induce an attack in those predisposed to gout, and a farther parallelism between gout and diabetes is thus established.

If, in consequence of simple imperfect assimilation, glycocine passes unaltered into the circulation, it may there be changed into carbonic anhydride and methymaline, which latter is instantly decomposed into ammonium, hydrogen, and oxalic acid. Thus may be developed the so-called oxalic diathesis, with all its accompanying nervous symptoms, not unlike those which are the precursors of gout, and which may be produced by errors of diet, and by the direct administration of oxalic acid. The effect of oxalic acid on the nervous system may be such as to intensify the force concerned in the production of urea, and so give rise to increased metabolism of the tissues and further formation of urea.

As to the application of these principles to the treatment of gout and uric acid gravel, moderate but not over exercise, tempered to suit the age, more for the young, less for the old, walking and riding are recommended; also a diet simple and nutritious, jellies and food containing gelatine being avoided, because the latter contains glycocine. Animal food, according to Dr. Latham, will not produce uric acid in a healthy system, as is shown by its absence from the urine of carnivora, but from all kinds of meat a certain amount of glycocine is produced, and even if the remaining nitrogenous part is converted into urea, the glycocine necessitates an increased elimination and consequently taxes more severely the powers of the kidneys. If these are weakened, the urea, and still more the uric acid, accumulates in the blood. The simpler the diet, the less tax there will be upon the kidneys. It may be farinaceous, with just sufficient nitrogenous food to satisfy the wants of the system, and in acute attacks, let that be in the form of milk, diluted if necessary.

Dr. Latham refers to the striking benefit and increased urinary secretion which result in some forms of albuminuria from skim-milk, the simplest of all diets. A further explanation of the benefits of such a diet, and a further confirmation of Dr. Latham's views, are found in urinalysis. Dr. John Marshall, of the University of Pennsylvania, in a series of analyses of the urine of persons upon a pure skim-milk diet, found that in the total secretion for twenty-four hours of such persons no appreciable amount of uric acid could be found. A fuller statement of Dr. Marshall's results may be found in the paper of Dr. Tyson, on the "Milk Treatment of Disease," published in the *Journal of the American Med. Assoc.*, for June 7th.

The accumulation of glycocine being thus diminished, when present, it is to be eliminated by such gentle laxatives as promote the discharge of bile from the intestines after it has been secreted. Such a laxative is calomel, and also rhubarb, a few grains with double the quantity of magnesia daily. The salines, by causing serous discharges, may carry off some of the poison from the blood, and relieve a congested liver.

Again, remedies should be administered that will combine with glycocine, and thereby prevent the formation of uric acid. Such is benzoic acid, which seizes upon the glycocine and converts it into hippuric acid, rendering the uric acid already existing in the blood more soluble. It may be given, as originally prescribed by Golding-Bird, in conjunction with phosphate and carbonate of sodium in cinnamon-water. Or, if given alone, compressed into a five-grain pill, of which two may be given at a dose.

In like manner, salicylic acid combines with glycocine, forming salicyluric acid. Dr. Latham prefers this to benzoic acid where there is no albuminuria, since he claims that it not unfrequently increases that condition. He says, too, that the true acid made from the oil of wintergreen must be given, and not the artificial one made from carbolic acid, and as much as can be borne without producing head symptoms; in rheumatic fever, 20 grains every hour until the patient complains of slight buzzing, and then from 45 to 60 grains daily for a fortnight. It too should be compressed into a five-grain pill, or it may be given with phosphate of sodium, which is not only a solvent for it, but for uric acid as well. In our own experience, however, the enormous doses of salicylic acid recommended by Dr. Latham, are not borne by the American stomach.

The alkaline carbonates are also of service in gout, although sometimes they cause oxalates to take the place of uric acid, which state continues as long as the glycocine passes unchanged into the blood, so

that measures must be continued to promote the normal metabolism of that substance.

Iodide of potassium is also useful in chronic gout and in gouty asthma. It does not prevent, but rather encourages the formation of glycocine through hydriodic acid, but it exerts a solvent action on the uric acid in the blood; while it is also useful in removing thickening in the tissues about the joints. It may be given in doses of 10 to 15 grains two hours after a meal, and Dr. Latham combines it with small doses of tincture of belladonna.

Chloride of ammonium, very useful in some gouty cases, acts similarly to iodide of potassium through its hydrochloric acid. The bilious headache (megrim), often relieved by common salt, is probably gouty in origin, while many of the mineral waters which have a reputation for the cure of gout, contain, in addition to laxative elements, chlorides, which may add to the virtues of the waters.

The time-honored colchicum is acknowledged by Dr. Latham to be useful, especially in acute gout, but he has no rational explanation to offer of its action. May it not also aid in the elimination of glycocine?

REVIEWS.

EXCESSIVE VENERY, MASTURBATION, AND CONTINENCE. THE ETIOLOGY, PATHOLOGY, AND TREATMENT OF THE DISEASES RESULTING FROM VENEREAL EXCESSES, MASTURBATION, AND CONTINENCE. By JOSEPH W. HOWE, M.D., etc. 8vo., pp. xv. 299. New York: Bermingham & Company, 1884.

IF everything is to be judged by the company it keeps, this title-page puts what has generally been considered a virtue in danger of losing its credit. Equally we might say, and hope as sincerely to find ourselves mistaken, that the author of these three hundred and more pages runs no little risk from the possibility that the old saw alluded to may be applied to him; for the majority of the books written to treat of debased animal passion have been the work of men whose general reputations have not been good at any rate, or who have suffered in the esteem of their fellows by an apparent relish for what is, to many, simply disgusting.

There are some things in the book before us which make it more than usually unpleasant for us to say just what we think. But there have been of late so many publications of this kind put upon the market that it looks as if there might be some particular evil star in the ascendant, and it seems proper to say, plainly and severely, what our offended moral sense dictates, in order that there may be the less likelihood that forbearance shall be mistaken for approval.

The book before us, like all of its class, has not even the merit of presenting its repulsive subject correctly. It perverts the truth, avers what is notoriously false, and spices these faults with narratives which have nothing to commend them to one's attention but their depravity. To obtain these, the author seems to have searched to some purpose the pages of Lallemand and of his own recent predecessor in this unsavory field—Hammond. They and he alike deserve, in our opinion, the most unqualified condemnation, and we sincerely wish all may have no admirers or followers. We should think ill of our profession did we not believe that, as there were two sons of old Noah who, when he was not himself, went backward and covered him with a mantle, to one who looked unblushingly upon his nakedness and went off to talk about it: so the mass of medical men—who must be familiar with much which others may not so much as name—take no pleasure in contemplating nastiness, and turn their faces from it whenever they can.

SOCIETY PROCEEDINGS.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, June 4, 1884.

THE PRESIDENT, J. M. DA COSTA, M.D., IN THE CHAIR.

DR. WHARTON SINKLER read the following paper on

A FORM OF NUMBNESS, CHIEFLY OF THE UPPER EXTREMITIES.

For several years, he said, I have observed in my service at the Infirmary for Nervous Diseases, in this city, and occasionally in my private practice, quite a large number of patients whose prominent symptom was numbness of the hands. The symptoms in these cases are quite regular and constant in their general characters. The patients are usually women, at about the change of life, although cases may occur in men, as will be seen from the instances given below.

The numbness generally begins in one or both hands and gradually extends up the arms. It may be felt in the feet and legs also. It is almost always most marked in the morning, before the patient rises. It is described as a "tingling," and "like pins and needles," or as if the limb "were asleep."

One patient, in whom the numbness was felt in both upper and lower extremities, said she felt like "a sleeping fool." Notwithstanding the numbness, there is but little loss of feeling to touch or pain, and usually the compass points are distinguished as readily in the affected part as in other portions of the body.

The numb member is weak, but there is no paralysis, and the weakness is transient. Often there is pain associated with the numbness. The patients sometimes think the hands are swollen at the time when the numbness is most marked.

I will give, briefly, the history of some typical cases of the affection. It must be borne in mind that I do not consider all cases of numbness as coming under this head. There are many cases of numbness met with which do not depend upon organic lesions of the nervous centres, and yet differ from those which I am now considering.

Case I.—Hannah R., æt. 30 years, single, coat-maker, applied at the Infirmary for Nervous Diseases February 6, 1872. Complains of numbness and pain in both hands and arms. They began three weeks ago in the hands, and the attacks now extend above the elbows. They are induced by sewing, and also come on at night. The numbness and pain begin in the ulnar distribution of the right hand and then extend to the rest of the hand and up the arm. In the left hand they are confined to

the forefinger. Sensation is accurate in the affected regions. The ulnar distribution is affected readily by slight pressure over the course of the nerve. There is some tenderness over the median nerve. There is no spinal tenderness. The pulse is feeble, and there is a slight murmur heard at the base of the heart. There is some rheumatic stiffness of both wrists, and decided difficulty in moving the right shoulder. Under the use of galvanism and a very strongly stimulating liniment to the arms, the patient was entirely relieved of the numbness and pain.

Case II.—Letitia M., æt. 48 years, applied at the Infirmary for Nervous Diseases July 5, 1878. Has always been a healthy woman, and has no history of rheumatism. About one year ago she noticed numbness in the right hand: at first in the thumb and first and second fingers, and occasionally in the other fingers. In the beginning it was felt only in rising in the morning, but latterly it has remained all day in the first and second fingers. It is always worse in the morning. About two months ago, she noticed pain at the base of the thumb like a sprain. It comes on with any movements of the arm, and ceases when the limb is at rest. Any movements which require pressure with the thumb bring on pain. There is slight pain on pressure over the median nerve. Sensation to touch and the compass points in the hand and arm are normal.

Case III.—Catharine O'C., æt. 50, washerwoman, applied at the Infirmary for Nervous Diseases June 22, 1880. Catamenia have ceased for some time. Six months ago began to have numbness in the left hip, which extended down the leg. Has had an attack in the right hand. It is worse in the mornings. Dynamometer, right 90, left 70. Ordered ext. ergot. fld. gtt. xx t. d. *July 14.* Returned, saying that she was much better.

Case IV.—Mary M., æt. 60 years, applied at the Infirmary for Nervous Diseases September 15, 1880. Two years ago she was cutting grass with scissors when she injured the forefinger of the left hand. This was followed by numbness of all the fingers, which extended up the arm. The numbness and tingling are now in both arms, and are also felt in the legs. They are most marked at night when the patient is in bed, especially if she lies upon her back. The sensibility of the fingers is good, but there is a slight loss to compass points. The numbness is most marked in the second and third fingers. The hands feel weak. Dynamometer, right 80, left 85. Ordered ext. ergot. fld. ʒss t. d. *October 13.* Much better. Dynamometer, right 100, left 100. Decreased ergot to gtt. xx t. d. *26th.* Not so well. Increased dose of ergot to gtt. xl t. d., and applied mustard plasters over spine every night. *December 8.* Dynamometer, right 115, left 100. Numbness very much less. The patient continued to improve, and when last seen, in May, 1882, stated that she was greatly relieved of the numbness, although it still occurred at times. If she allowed the arms to lie close by the side when asleep, they became numb. If they were extended, this did not take place.

Case V.—Mrs. B., æt. 50, nurse, applied at the Infirmary for Nervous Diseases November 25, 1881. Menopause eighteen months ago. Is in good health with the exception of numbness of the hands, which began several years ago. There is no assignable cause for the numbness. The numbness is always in the ulnar distribution, and occasionally in the median distribution of hand, and extends up the arm. It is decidedly most marked in the left hand and arm, and is occasionally felt in the left foot. The position of the arms had no influence in bringing on an attack of numbness, but prolonged exertion of the arm will induce it. There is always loss of power of the arm after the numbness has passed off. The dynamometer shows a difference of 20° in favor of the right hand. The patellar reflexes are good. Heart normal.

Case VI.—Mrs. J. æt. 51, appplied at the Infirmary for Nervous Diseases February 15, 1884. Two years ago used her right hand very much. Then began to have numbness in the fingers and hand. Following this there was a burning pain. Her general health has been good, but she sleeps badly. The numbness begins in the fingers, and it is followed by a burning pain which also begins in the fingers, and extends up the arm as far as the elbow. It is most frequent in the early morning. There is slight tenderness on pressure of the ulnar nerve at the elbow. No loss of sensation to touch or to compass points. Dynamometer, right 80, left 95. Ordered ext. ergot. fld. gtt. xx t. d. *February 25.* Returned, saying that the pain and numbness are much relieved. Continued same treatment. *March 10.* For the past few days symptoms have been worse. Is sleeping badly. Ordered to stop ergot and take sodii bromid. grs. xv t. d. *April 17.* Reports that she was not so well while taking bromide. Returned to ergot of her own accord yesterday, and slept well last night. The numbness is also much less.

Case VII.—Mrs. M., æt. 50, widow, consulted me July 13, 1881. Has enjoyed good health and worked hard until recently. Catamenia regular until three years ago. Then she began to have numbness and pricking of the feet, with starting of the legs while in bed. The numbness then extended to the hands and arms. Numbness is now worse in left arm, but a month ago the right arm was most affected. The wrists are painful, and feel as if sprained. If the arms hang down, the numbness is increased. The hands and legs become swollen. She has frequent "flushes of heat" through the whole body, and she then becomes flushed and warm, the sweat starting out freely. Her sleep is interrupted by the starting of the legs. She is a stout, florid woman; has a good appetite, and no dyspepsia or constipation of the bowels. The urine was found to be free from albumen. She is very nervous and often has headaches. The symptoms were markedly relieved by bromide of sodium and ergot.

Case VIII.—Charles E. S., æt. 34, carpenter, applied at the Infirmary for Nervous Diseases August 30, 1878. For a year he has had a sense of general fatigue, and for several months he has had pain in the right shoulder. He has worked very hard, both mentally and physically, for some years. Since last fall he has felt very sleepy all the time. A few days ago noticed twitching of the right hand, and at night was awakened by pain and numbness in the palm of the hand and twitching of the fingers. Since that time the numbness and pain have continued, but are worse when he lies down, so that he is prevented from sleeping. He has had pain in the cervical region of the spine. The patient is obliged to use the right hand a good deal, as, for in-

stance, in planing, and this brings on the attack of pain and numbness. On examination, no twitching is seen, but the patient says there is a feeling as if the fingers were twitching. There is no loss of sensation in the right hand to touch or compass points. The right hand has become weaker. Dynamometer, right 130, left 130. Appetite poor; tongue furred; tendency to diarrhœa. The urine is free from albumen. Ordered potassii iod. gr. x, vin. ergot. f℥j t. d. *September 6.* Is better. Can sleep now, but is awakened about 5 A.M. by pain and numbness in the right arm and shoulder. *11th.* Improving, but the early morning pain and numbness continue. Increased wine of ergot to f℥iij t. d. *18th.* Now sleeps very well. No early morning pain and numbness. This patient remained under treatment at intervals until September, 1881. He had occasional relapses; the attacks being almost invariably brought on by overuse of the hand. At times the numbness extended to the right leg. The pain in the back of the neck was sometimes felt. The last note of the dynamometer was right 155, left 150. The treatment consisted in the free administration of ergot, and, after the subsidence of the symptoms, phosphorus, strychnia, and iron were given for long periods. Blisters were applied over the cervical spine several times.

Case IV.—Mr. H. P. M., æt. 30, married. This patient had an attack of poliomyelitis anterior in 1877. I related his case at length in The American Journal of the Medical Sciences for October, 1878. He made a complete recovery from the paralysis, and enjoyed excellent health until March, 1883. At this time he came to me complaining of numbness in the hands. The attacks came on in the early morning, and would waken him from sleep. At first he ascribed it to sleeping with his arm extended above his head, but it continues to occur no matter in what position the arms are. The patient is in good general health. No indigestion or rheumatism. The sensation in the hands is normal; the grip is weaker than before the numbness began. Dynamometer, right 156, left 120. He complains of an area of coldness in the right thigh above the knee. There is no anæsthesia or numbness in this region. This case was treated at first with iodide of potassium and massage, and later with strychnia. The symptoms were gradually relieved, and the strength of the hands returned. On April 7, 1883, dynamometer marked right 160, left 130. He still had occasional returns of numbness until October, 1883. At this time, however, the numbness was confined to the tips of the fingers, and did not disturb him until late in the morning.

Mr. M. consulted me again on March 17, 1884; he stated that he had remained free from numbness until lately. The attacks came on as before, *i. e.*, in the early morning, waking him at about 5 A.M. The numbness is worse in the right hand, and this hand is relatively weaker than the left. Dynamometer, right 142, left 136. The hands feel as if they were swollen in the early morning. Ordered ext. ergot. fld. gtt. xxx t. d. *April 4.* Patient reports improvement. Numbness comes on later in the morning. Now ordered strychniæ sulph. gr. $\frac{1}{30}$ t. d. Ergot stopped. *26th.* Better; sleeps until 6 A.M., but is then wakened by the numbness. Stopped strychnia. ℞. Syr. d'ergotinine (Tanret's) f℥j t. d. *May 6.* Patient thinks last prescription has had more decided influence in relieving the numbness than anything he has taken; the numbness comes on later every day. Dynamometer, right 158, left 142. *18th.* Patient now has no numbness.

It will be seen that of the female patients whose cases I have given, their ages were between forty-eight and sixty years, with the exception of one who was thirty years. In this case the disorder was induced by the nature of her work, which was constant and hard sewing. The ages ranged as follows:

1	aged 30 years.	1	aged 51 years.
2	" 48 "	1	" 60 "
3	" 50 "		

In two patients, Cases I. and VII., there were evidences of rheumatism, but in none of the others were there any symptoms of rheumatic trouble. In Cases I., IV., and VIII., the origin of the trouble seemed to be in overuse of the limb first affected. Indeed, in Case VIII. the affection at first seemed like a low form of an ascending neuritis, but afterwards the symptoms were more general.

Most of the patients were in good general health, but some were anæmic or overworked.

The numbness in most instances was in both arms, occasionally it was found in all of the limbs, and in three cases in one arm alone. The ulnar and median distributions were most frequently affected.

Pain was associated with the numbness in several patients. It was not an acute pain like neuralgia, but, as one patient expressed it, like the pain which comes when a limb is getting over being asleep. Tenderness over the ulnar or median nerve was observed several times. There was usually some loss of power in the parts involved. The dynamometer showed several degrees difference between the hands in the cases when only one limb was affected. The duration of the affection was from a few months to several years. One of the patients had suffered from the disorder for two years before coming under observation, and at the end of a year and a half still had occasional attacks.

Dr. Weir Mitchell, in a lecture on "The Symptom Numbness,"[1] and later, in a chapter in his work on *Diseases of the Nervous System*, has described several varieties of numbness. Most of his cases were in anæmic or hysterical persons, and the symptom yielded under a course of treatment which tended to improve the nutrition and *morale* of the patients. He refers to cases in which the numbness came on during sleep, and remarks that this is a form "which belongs to the night." He finds that the numbness in the cases he has seen is frequently hemiplegic in character, and alludes to the fact that "some persons who have gotten pretty well of a hemiplegia of organic cause are liable to waken out of sleep with numbness and lessened power of the side once palsied.

Dr. James J. Putnam, in a paper read before the American Neurological Association,[2] treats at length of a series of cases of "paræsthesia mainly of the hands." He bases his paper upon the notes of thirty-one cases, and the description he gives resembles those which I have related. He finds that most of his patients were women, and almost all were in middle life, but he does

[1] Med. and Surg. Reporter, Dec. 2, 1876.

[2] Archives of Medicine, vol. iv., No. 2, Oct. 1880.

not remark upon the fact that they were about the period of the menopause.

Dr. Putnam suggests that the possible cause of the affection is, "alterations of the blood-supply of the smaller branches or terminal filaments of the sensitive nerves supplying the affected districts."

The treatment of this writer consisted in the use of galvanism, phosphorus, strychnia, bromide of potassium, and several other drugs. He did not think that he had had sufficient opportunity to test the value of the different remedies, but seems to have found phosphorus of more value than any other one means used.[1]

Dr. J. A. Ormerod has described twelve cases[2] which very closely correspond to those which have come under my observation. All of his patients were women, and the attacks of numbness began to come on about the cessation of the menses. Three of his cases were rheumatic, and in some the trouble proceeded from the nature of their work. Bromide of potassium afforded marked relief in many of the cases. Dr. Ormerod compares this affection to the deadness of the fingers which some persons experience after exposure to cold, and therefore ascribes it to vascular spasm.

It has seemed to me that in these cases there is probably a condition of hyperæmia either of the nerve-trunk or of a portion of the cord. In some cases I think the hyperæmia is confined to the nerve-trunks or to some of the terminal filaments of the sensory nerves, but in others it seems not unlikely that the cervical enlargement of the cord becomes hyperæmic or congested, from the fact that the numbness is often bilateral. The circumstance that the affection comes on at night seems to me to strengthen the view of the pathological condition being one of hyperæmia, for the supine position favors an increase of blood in the cord and the nerves of the extremities. I have seen patients in whom the numbness would come on if they lay down and fell asleep even for a short time in the day.

Women at the change of life are more prone to hyperæmias and congestions than at other periods of life, and they are the most frequent subjects of this form of numbness.

In several of my cases ergot gave marked relief, and Dr. Ormerod found bromide of potassium the most successful therapeutic means he used. Both of these remedies are believed to diminish the blood-supply in the nervous centres. It is true that Dr. Putnam found phosphorus the most useful drug in his cases, but in one of those which he reports the remedy failed, and another was relieved by bromide of potassium.

From my experience in these cases, I should say that the prognosis in middle-aged women was not good for permanent relief. The numbness can generally be greatly benefited or stopped for the time, but it is liable to return. In those cases in which the trouble has been induced by overwork of the part, one can almost surely promise permanent cure if the cause can be removed.

With regard to treatment, as indicated above, ergot has proved the most useful medicinal means I have employed. Massage and spinal galvanism are always useful adjuvants, and so are all means which improve the general health. Bromide of potassium has helped some of my cases, and one patient was much benefited by sinapisms over the spine. It was found advantageous in most of the patients to give strychnia for a time after the disappearance of the numbness.

[1] In a note recently received from Dr. Putnam, he says that he has lately found lead in the urine of one of the patients referred to in his paper, and thinks that it should be looked for in all cases of numbness.

CORRESPONDENCE

ETHERIZATION BY THE RECTUM.

To the Editor of The Medical News.

Sir: From the first publication in regard to the production of anæsthesia by introducing the vapor of ether into the rectum, I was satisfied that it was not a new process, but dated far back of Yvrsen, of Copenhagen, or Mollière, of Lyons. It was associated in my mind with the name of Pirogoff, but I searched my notes and references in vain. Having now stumbled upon the evidence of an earlier use of this method than the present time, I send it for the benefit of your readers, and with it all the references to the original papers, that those interested, and having access to large libraries, may study the subject.

The method is mentioned in Bernard's *Leçons sur les Anesthétiques et sur l'Asphyxie*, Paris, 1875, p. 61. After stating and illustrating the proposition that all anæsthetics must gain access to the blood to produce their effect, the author says:

"In the same manner it is possible to produce anæsthesia by introducing the vapor of ether freely into the rectum, but it is a practice little followed, very uncertain, and which is recalled only as an historical curiosity. The possibility of anæsthesia by the rectum having been indicated by Roux (*Acad. des Sciences*, 1er Fevrier, 1847), it has been since established as to animals, by Vincente y Hedo (*Ibid.*, 17 mai, 1867), and by Marc Dupuy (*Ibid.*, 5 avril, 1867). It is M. Pigoroff, however, of St. Petersburg, who has tested this proceeding on patients (*Recherches pratiques et physiologiques sur l'Etherization*, St. Petersburg, 1847). According to Pirogoff, anæsthesia comes on rapidly, without preceding excitement; scarcely has the vapor of ether penetrated the rectum, or at the end of one or two minutes, when it can be detected in the breath. A short time after the etherization, a large quantity of gas mixed with the vapor of ether escapes from the rectum. . . . Meantime, this method has not been adopted; the attempt was only inspired by the exaggerated fears of inhalation of anæsthetic vapors which prevailed at that time."

If some one of your readers would translate and publish Pirogoff's paper to which reference is made above, he would confer a favor upon the profession, or at least furnish a very interesting article for perusal at this time.

Yours, J. C. R.

Dayton, Ohio.

THE DANGER OF GLASS VAGINAL DILATORS.

To the Editor of The Medical News.

Sir: May I add a recent experience of mine to that of Dr. R. Tauszky as a protest against the use of glass in the vagina? I was summoned hastily about mid-

night to a patient of a prominent gynecologist, who happened to be out of the city, and found that the lady had been using glass dilators, under his supervision, to maintain the results of an operation for vaginismus with rigid hymen. Whilst she was lying quietly in bed the glass broke in her vagina with an audible report, although it had been in her some minutes and had not been dropped or exposed to any violence. It had been used *secundum artem*. Much difficulty was encountered in extracting the end, which had separated as a disk with upper edges rounded and the lower sharp, but by the use of the handle of a large spoon in the manner of a Sims's speculum and putting a finger in the rectum, we succeeded without causing serious laceration. I have once or twice seen a tumbler quietly standing on a table unaccountably fly to pieces without apparent external agency, and suppose the breaking of the dilator was of parallel origin, although I know of no way of explaining the phenomenon.

Yours, etc. . . . .

NEWS ITEMS.

CHICAGO.

(*From our Special Correspondent.*)

The Local Conference of Health Commissioner De Wolf and Chicago Physicians on the Cholera Situation.—Commissioner De Wolf opened the meeting, in the City Hall, Friday, July 25, by thanking the physicians for responding to his invitation. He did not design nor attempt to shift or transfer any responsibility which the duty of his office imposed upon him to other shoulders. But he well understood that, when a community was disturbed—as all communities were at this moment—it was very important that mistakes should not be made. He also understood that any act which they approved, or any measure which they suggested, would be precisely the right thing at the right time, and would meet with the approval of the community.

Is the city of Chicago, to-day, in a satisfactory condition from a sanitary standpoint? There was only one answer. It was not, and never would be in his day or theirs. There were large tracts of territory in this city which must fill any intelligent mind with alarm in the face of an epidemic. For example, the Fifth Ward, with 57,000 people, and the Fourteenth Ward with 67,000 people, were in a shocking condition. In the Fourteenth Ward, 30,000 people lived on unsewered land, from three to five feet below the surface of the street, the privy vaults and house sites were saturated with water eight months in the year, the ground receiving the sewage from the dwellings and the seepage from the vaults; cottages of four rooms, having a family in each room, with many children—packed like herrings in a box. Such conditions were far from sanitary conditions.

When, on June 23, 1883, cholera appeared at Damietta, he felt reasonably assured that this atrocious disease had commenced its journey over the civilized world, and from that day he had in every way done what he could to prepare for its advent. Last year, thirteen miles of sewers were put down; this year, nine miles, so far, and seven more were to be laid. Last year the tenement force was increased, and he commenced a thorough and complete examination of the tenement houses of the city. Of these, 4644, containing 125,000 people, had been examined and their sanitary condition improved; 3973 privy-vaults had been cleaned; the department had in operation 144 two-horse teams cleaning the alleys, and the Department of Public Works gave employment to 151 men and 25 teams, with two men to each team in cleaning gutters. This work was independent of the ordinary street-cleaning, which was done by contract. This work was pursued under difficulties; in some sections of the Fifth Ward, the gutters were below the surface of the sewers. There were miles of sewers so placed that neither house-sinks nor gutters could be connected with them until extensive areas of country were raised to the sewer-level. It was necessary to place these sewers at the level that they might be connected with the general sewerage system.

Individual opinion was asked upon the following subjects:

I. Quarantine. While a firm believer in it, he had absolutely no confidence in the ordinary operation of quarantine. For example, Toulon placed what is called a military cordon sanitaire about the city, and yet through that line of soldiers and police, forty thousand of the lazzaroni, each with a bundle of rags, dispersed themselves over Europe. In 1873 quarantine was observed in New York and Boston—a quarantine of the individual—but that individual had with him a trunk or a box infected with cholera germs from the cholera districts, and cholera appeared in De Peyster Street, New Orleans, and at three or four points in the Northwest from the exposure of this clothing. The quarantine which observed the individual and not the condition of his clothing, was a delusion and a fraud. If cholera appeared on our coast, he should regard it his duty to place a medical inspector —an accomplished man—on every immigrant train coming into the city, to find out where the immigrant proposed to stop. If in Chicago, the baggage should be taken possession of and fumigated. If they were merely passing through the city, no attention should be paid to it. It was possible that at the conference to be held at Washington, August 7th, some action might be taken which would relieve the city authorities from these observations. The placing of these young medical men meant a large expenditure of money. While there was no limit to the amount he could receive for the management of an epidemic, if it appeared, the money must be spent intelligently as well as vigorously, and if they approved this disposition to which he had referred, it would be so spent.

II. Hospital accommodation. There was the small-pox hospital, four miles from the city, which was in admirable order, and under the care of an order of the Catholic sisterhood. Should that hospital be utilized for cholera purposes if the disease appeared? Would the private hospitals be ready and willing to open their doors, and set aside space where we might put cholera patients unable to take care of themselves? If not, would they advise the erection of temporary hospitals in different parts of the city?

III. Division of the city into districts, and the appointment of medical officers. He had divided the city in his mind into forty districts, into each of which, when cholera appeared on the coast, he proposed to put a young, intelligent medical man. He had most of them in mind, and would complete the list before the end of

the week. He proposed to call them together and confer with them touching their duty as health officers in relation to an epidemic of this kind. He would be in constant communication with them by telephone. At the City Hall there would be on duty at all times an ample ambulance service. When there was occasion for it, this could be put in operation at twelve hours' notice.

IV. Resources for disinfection. The resources for disinfection were ample and complete. He could command five thousand gallons of chloride of zinc every day, if necessary. This chloride of zinc was a waste product in connection with certain manufacturing interests in Chicago, and would cost the city nothing.

As to the condition of the city to-day, he claimed that the inspection of tenement houses, the putting in of sewers, and making connection, and cleaning of privies was a legitimate sanitary work. It did not appear on the surface, but it told when the mortality list of the city was reviewed. The death-rate in Chicago had been steadily diminished from 26 in 1000 to less than that of any city of its size on the globe. He claimed that Chicago was in relatively good shape to meet the shock of any epidemic. In reply to questions, Dr. De Wolf said that the smallpox hospital could accommodate two hundred patients, but that the distance was great and the roads were bad.

Dr. N. S. Davis approved the suggestions relative to the quarantine, but thought they would be ineffective. He suggested that when a train was inspected, the results should be telegraphed ahead, in the direction it was going, so that the people of other cities might also derive a benefit from the inspection. As regards hospital accommodations, he desired to encourage the treatment of patients wherever they happened to be seized, as removal was likely to hasten death. He thought there was no ground for expectation of cholera this year. It was not America's turn. It did not come here, as a rule, until the third year after it appeared in the distant East.

Dr. W. H. Byford thought all quarantine was an experiment, and of doubtful utility; he approved the plans of the Health Commissioner. As to hospitals, he favored the erection of temporary ones of boards. Tents would be better.

Dr. H. A. Johnson thought that the measures of quarantine to be established here should depend upon those taken elsewhere. He thought it bad policy to wait until it had got to Hyde Park in trains coming to the city. In a city, in the midst of a continent, besieged by an enemy whose approach must be guarded from every quarter, it will be found difficult to do anything. He approved the idea of temporary barracks in place of regular hospitals.

Dr. Ephraim Ingals, took a sanguine view of the situation, and thought Chicago had no more reason to fear a cholera epidemic, than she had to have apprehension of a second fire.

Drs. R. N. Isham, R. Ludlam, J. B. Ross, Ernst Schmidt, J. H. Etheridge, J. E. Gilman, and Wickersham, expressed approval of the Health Commissioner's plans.

The following resolution was then offered, and adopted:

Resolved, That we have been informed of the plans and means which the Commissioner of Health proposes to adopt in case an outbreak of cholera should occur in our city, and we approve of the same.

The very pertinent question—"Why is the water of the North Branch pumped into the lake?"—was referred by the Commissioner of Health to the Commissioner of Public Works, who was not present.

Cholera Notes.—The cholera mortality at Marseilles and Toulon is diminishing, but the disease has spread to Arles, Mouillon, La Valette, and Aix, and isolated cases continue to be reported in various parts of France, some widely distant from the infected district. At Vintimiglia, in Italy, ten deaths have been reported, at Panealieri seventeen cases, and at Spizzia two deaths.

At Marseilles, the daily mortality has diminished from 43 on the 23d ult. to 23 on the 29th.

The classification of the deaths from cholera, according to the nationality of the victims, gives the following results: French, 798; Italian, 322; Spanish, 13; Greek, 9; English, 1; Austrian, 1; German, 1, and American, 1.

The disease is reported not to have the same virulence that has characterized previous outbreaks, and that it appears to have attacked sickly individuals rather than whole sections of the population. It is estimated that the total number of deaths at Marseilles since the outbreak appeared reaches 1000, and that 500 cases have been cured. At Toulon, the total mortality to July 26 is 593.

The French Academy of Medicine proposes to hold an international congress to discuss the prevention and cure of cholera. Dr. Koch has asked that the congress meet in Berlin.

British Precautions.—The Duke of Cambridge, the Commander-in-Chief of the British Army, has issued additional orders for the taking of precautionary measures against cholera in the army. He has directed the barracks throughout England to be placed in the best sanitary condition possible. He has also given orders for the creation of a system of medical relief and for the removal of the troops into camps in case the cholera appears among the soldiers.

The steamship St. Dunstan, which arrived from Marseilles on July 18th, having two cases of cholera on board, left quarantine at Liverpool on July 23d and was docked. She had been previously thoroughly fumigated to destroy all possibility of infection.

Cholera Precautions in France.—The Comité Consultif d'Hygiène Publique of France, have promulgated the following rules for protection against cholera:

Excessive fatigue, either by travelling or for pleasure, as well as by prolonged wakefulness and cold baths of long duration, should be avoided. Chilling of the body, especially during sleep, drinking large quantities of cold water, are very dangerous in time of cholera. The use of bad water is one of the most frequent causes of cholera. When not perfectly sure of the good quality of the water used for drinking and cooking purposes, it is better to boil a supply for each day, as boiling makes it perfectly safe. A small quantity of tea, hops, or bitter or aromatic plants, or wine, may be added to the water to be boiled. The following drink is recommended as excellent for quenching the thirst

without drinking a large quantity of fluid: Rum, 40 parts; alcoholic tincture of gentian, 4 parts; fresh water, 1000 parts, by weight. It is better to filter this through charcoal. Table mineral waters are excellent.

Bakers should be forbidden to make bread with water from wells placed inside of a house, when latrines and manure heaps are sufficiently near to soil the water, and they should be absolutely forbidden to use such wells in time of cholera.

There is no reason why fruits should not be used in moderation, provided they be of good quality. They should always be peeled, and it is better to eat them cooked. This applies also to vegetables, which should be cooked. Every indiscretion of diet should be avoided. It is very dangerous to drink much alcoholic liquor; complete abstinence is better than a slight excess. Ices and iced drinks taken rapidly during digestion, or while the body is perspiring, are liable to cause choleraic attacks, and should be avoided.

Precautions in case of an attack. The least digestive troubles may invite an attack of cholera, consequently they should never be neglected, and a physician should be sent for immediately, as an attack may be prevented or arrested by timely active treatment.

Nurses for cholera patients. No person in attendance upon a cholera patient should go without rest for more than twelve hours. They should have a double quantity of wine, and of coffee at night. Every day, after the morning visit, the physician should see to the state of health of these persons, and prescribe, when necessary, rest and suspension of duty.

Transmission of cholera. Cholera is most frequently propagated by vomited matter and alvine evacuations; and these discharges are very little less dangerous in mild cases than in the most severe. They should be disinfected, and removed from the sick-room as soon as possible.

Disinfection. Every latrine in a house may be poisoned, when emptying into one discharges which have not been disinfected. The disinfectants to be recommended are first, sulphate of copper, next, chloride of lime, and chloride of zinc. Carbolic acid and copperas are insufficient. To each alvine evacuation or each quart of liquid matter, a large glassful of the following solution should be added: Sulphate of copper, of commerce, ʒxiij; water, Qj; or a small coffeecupful of chloride of lime in powder (about ℥xx); or a solution of chloride of zinc (1 to 100). It is best to place these in the bottom of the vessel intended to secure the dejections.

Linen. Soiled body- or bed-linen should be plunged, before being taken out of the room, into a tub containing either a gallon of the sulphate of copper solution, or two cupfuls of dry chloride of lime. They should be put into the tub, and wrung out—about half an hour in the copper solution is sufficient. This solution should be made fresh every day. When removed from the solution the linen should be immediately boiled, before using soap. Disinfection may also be performed with sulphur in the following manner: The clothes are hung up in an empty closet, all the openings of which are thoroughly closed, and a little water is sprinkled on the floor to make the air moist; ʒvij of flowers of sulphur to the cubic yard are then burned. The sulphur should be placed in a vessel placed at the bottom of a small basin half full of moist sand. The sulphur is lighted and the person leaves the room immediately, to return and open the closet in about twenty-four hours. When the clothes are very much soiled, they should be burned.

The floors. The soiled spots on the floors and drapery about the room should be immediately washed with a rag dipped in the copper solution, or in milk of chloride of lime, made by mixing a spoonful of the dry lime with a quart of water. The rag should then be burned.

The beds. So far as possible, the beds occupied by cholera patients should be protected by paper to prevent soiling of the mattresses. The paper should be burned afterwards. Mattresses touched or soiled should be moistened by means of a rag or a piece of wadding or tow, with the copper solution (1 part in 5 of water) or with the chloride of lime solution (a spoonful of dry lime to a quart of water). They should afterwards be removed, in special vehicles, and disinfected in an oven, either by steam or heat, 220° F. If this cannot be done, they should be placed on stands in a close room and disinfected by burning sulphur, not less than ʒvij of flowers of sulphur to the cubic yard of space in the room.

Water-closets. Twice a day, in houses in which there is cholera, two quarts of the copper solution should be emptied into the basins, or two cupfuls of lime in two quarts of water. A cupful of the copper solution or of solution of chloride of zinc should be emptied every evening into the drain-pipes about the house. Wherever it is possible, siphons or U-tubes should be attached, so as to prevent the entrance of gas into the house.

Provisions and everything to be eaten should be kept in tight cases, and every day half a glass of the copper solution should be poured over their surface, or one or two spoonfuls of chloride of lime, in powder. The kitchen refuse should be placed every day in a close metallic case, and sprinkled with chloride of lime before night. Every morning this case should be emptied by the city carts, a quantity of chloride of lime being placed at the bottom of the case when it is emptied.

The following are the general rules for public hygiene:

Public assemblages. In time of cholera there should be no assemblages of people, as in this manner the disease may be easily propagated.

Accumulations of filth. The accumulation of dirt and filth of any kind in the neighborhood of houses, should be strictly prohibited. They should only be disturbed and removed after having been disinfected with one of the materials mentioned above. Nor should any stagnation in sewers or drains be allowed; they should be disinfected and flushed. Scavenging should only be done with hermetically sealed receptacles, working by steam, and burning the gas under heaters. After each operation the place should be disinfected. All drains should be supervised and disinfected by the public authorities.

Compulsory notification. The immediate notification to the authorities of every case of cholera, should be obligatory.

Transportation of cholera patients. When a case occurs in a hotel or lodging-house, the authorities should be at once notified. The patient should not remain in the house, even for twenty-four hours, but should be carried to a specially provided place.

Disinfection of rooms. A room which has contained a cholera patient, even for the shortest time, should be disinfected with sulphur.

Disinfection of infected apartments. The room occupied temporarily by a cholera patient should not be occupied again until it has been completely disinfected by burning ʒvij of sulphur to the cubic yard.

Special ambulances. When several persons occupy the same room and one becomes infected with cholera, he should be immediately taken away in a hospital or special ambulance, to some place where the chances of recovery are greater and of infecting the others are removed.

Inspection of houses. In every house in which a case of cholera occurs, an immediate inspection should be made by a municipal officer, first to ascertain the true nature of the attack, and then to take active measures for disinfection. If it has not been thoroughly disinfected, it should be disinfected anew, the lodgers being compelled to vacate for twenty-four hours.

Laundries. Public laundries should be under the strictest supervision, and particular care be taken that the clothes of cholera patients are not washed together. As stated before, these should be thoroughly disinfected before being washed.

Distribution of disinfecting materials. Each police station should be a depot for the storing of disinfecting materials, put up in bottles or packages, of flowers of sulphur, dry chloride of lime, pulverized sulphate of copper, and solution of chloride of zinc, 45 per cent., with labels clearly stating how they should be used. These should be gratuitously distributed to persons having an order from a physician or a municipal officer.

Carriages. A sufficient number of carriages should be set apart for the sole purpose of conveying cholera patients. They should be disinfected every day. Special ambulances and urgency rooms for the temporary use of cholera patients should be furnished by the authorities.—*Gazette Méd. de Paris*, July 12, 1884.

Precautions Elsewhere on the Continent.—It is stated that the running of through coaches on the railways between Germany and France will be stopped on account of the cholera.

The Swiss Federal Council has decided not to stop the annual military training on account of the cholera.

A cablegram from Athens states that the steamer "Tiger," belonging to the Messageries Maritimes, from Marseilles, arrived off the Piræus, on July 27, with two cases of cholera on board. Admittance to the port was refused, and the steamer departed for Smyrna.

The *Wiener medizinische Presse*, of July 13, in an editorial article, questions if the meeting of the International Medical Congress should not be put off on account of the danger of propagating the cholera.

Precautions in the United States.—At the annual meeting of the West Virginia State Board of Health held on the 22d ult., the Secretary, Dr. James E. Reeves, was instructed to adopt such means as might seem to him best to protect the State from cholera.

Health Commissioner Stevenson, of St. Louis, will ask the Municipal Assembly, which meets on August 1st, for an appropriation to close all the wells in the city as a sanitary measure. Other measures will also be taken to place the city in a thoroughly clean condition to meet any possible appearance of cholera this season. A number of special inspectors are now giving private premises a thorough examination, and the entire police force has been put under strict orders to enforce all laws regarding nuisances.

An application was recently received at the Treasury Department for the admission at the port of New York of a consignment of rags, which had been shipped at Marseilles in May last. The vessel showed a clean bill of health, and had passed quarantine at New York. The application was denied on the ground that the order prohibiting the entry of rags from infected ports was imperative, and allowed no discretion.

Pasteur's Criticism of Koch's Views on Cholera.—*Le Figaro* has interviewed Pasteur regarding Koch's views of the cholera in France, and he replied, in writting, as follows: All the prophylactic measures against cholera which the press has reported as having been indicated by Dr. Koch at Marseilles and Toulon, are precisely those which have been recommended since the time when it was shown that cholera was principally transmitted by the dejecta of the cholera patients.

There is, however, one very new point in the instructions of Dr. Koch. He condemns irrigation and drainage by water in the gutters, and states that all causes of humidity are favorable to the propagation of the epidemic. We cannot view this proposition in the same light. If there are cholera microbes in the streets, or in a room, or on dry soiled linen, and these microbes have become so dry as to be non-viable, certainly sprinkling them will not render them viable. If, on the contrary, their state of desiccation is such that humidity favors their return to life, they should be moistened, as they will thus be rendered less susceptible of being carried about by the wind. In fact, if they are left in this state of relative dryness, and are not dead, the least movement will convey them to our mucous membranes, where they will find the moisture necessary for their life.

This logic appears to him incontestable, and proves how ill-founded is the opinion of Dr. Koch. Who will dare to enter, he asks, to sleep and eat in a room in which a cholera patient has died, and in which the linen and other clothing has been left dry for several days? "The objects soiled by the dejecta should be cleaned with dry linen, which should then be burned," says the report. This appears impracticable to me. A vase or marble is only with great difficulty cleaned with a dry rag; but it is not possible to clean cloth in this way. "Burn it," adds the report. My advice is different. It is well known that in burning linen small particles become detached and float about the room before being thoroughly burned. I prefer to plunge it into boiling water—the result is the same. Finally, Dr. Koch advises that the apartments in which cholera patients have died be left uninhabited for six days. On what does he base his opinion that the danger does not exist on the seventh day? This is entering into the domain of superstition. —*Gaz. Méd. de Paris.*

Yellow Fever.—The Consul at Guaymas, Mexico, reports to the Secretary of State that "the report of yellow fever at this port during the month has been greatly exaggerated. There is no doubt but what there

is a malignant type of malarial bilious fever; during the month eleven deaths are reported from this disease, which is called by some yellow fever. No foreigners have, as yet, died from it in the month. The port authorities still give clean bills of health to all vessels departing."

At Havana the yellow fever is slightly on the increase, with a reported mortality of twenty-three for the week ending July 26.

THE S. D. GROSS PROFESSORSHIP OF PATHOLOGICAL ANATOMY.—Dr. Richard J. Dunglison, Treasurer, Lock Box 1274, Philadelphia, acknowledges the following additional contributions to this fund:

W. L. Conyngham, Esq., Wilkes Barre,	$200
Dr. N. Bozeman, New York,	100
Dr. Wm. Pepper, Philadelphia,	100
Henry C. Lea, Esq., Philadelphia,	100
Dr. Frank Woodbury, Philadelphia,	50
Dr. C. Ernest Kamerly, Philadelphia,	25
Dr. James Graham, Philadelphia,	25
Dr. Hunter McGuire, Richmond, Va.,	25
Dr. D. W. Cheever, Boston,	20
Persifor Frazer, Esq., Philadelphia,	20
Dr. B. A. Watson, Jersey City, N. J.,	20
Dr. John Graham, Philadelphia,	20
Dr. Wm. Ashbridge, Philadelphia,	10
Dr. Horatio R. Bigelow, Washington, D.C.,	5

JEFFERSON MEDICAL COLLEGE.—DR. ROBERT E. ROGERS, Professor of Medical Chemistry and Toxicology in this institution, has just tendered his resignation of the Chair, to which he was elected in 1877.

AMERICAN PUBLIC HEALTH ASSOCIATION.—The twelfth annual session of this Association will be held at St. Louis on October 14–17, 1884, under the Presidency of Albert L. Gihon, M.D., U. S. A.

THE BRITISH MEDICAL ASSOCIATION.—The annual meeting of this Association was held at Belfast, beginning on Tuesday last, under the Presidency of Dr. James Cuming. Additional interest it was anticipated would be imparted to the proceedings by the presence of a number of distinguished foreigners, who had announced their intention to be present. From America, were expected Drs. Austin Flint, L. A. Sayre, and A. Jacobi, of New York; E. M. Moore, of Rochester, and S. J. Jones, of Chicago. From the Continent, Prof. Benedikt, of Vienna; Prof. Zehender, of Rostock; Dr. Cordes, of Geneva; Dr. Pozzi, of Paris; Prof. Gayet, of Lyons; Dr. Dujardin-Beaumetz, of Paris; Dr. Drummond, of Rome; and Dr. Grant Bey, of Cairo.

OBITUARY RECORD.—PROFESSOR E. JAEGER VON JAXTHAL. The Vienna journals announce the death of Prof. Jaeger, the celebrated oculist, at the age of sixty-six years. He took his degree of Doctor in Medicine in 1844. Until 1849 he served as surgeon in the Austrian Army, when he opened a private dispensary for the treatment of diseases of the eye. In 1853 he was appointed Privat-Docent for Ophthalmology in the University of Vienna, and was raised to the Adjunct Professorial Chair in 1857. In the same year he was appointed Ophthalmologist to the General Hospital, of which he remained chief ophthalmologist until his death. In 1883 he was appointed Professor in the University. Jaeger's scientific writings are known and read in every language, and his test-types are used by almost every ophthalmologist in the world. He was an original thinker, and a skilful operator.

——M. BOUISSON, the eminent surgeon of Montpellier, has recently died. He was at one time a military surgeon, and contributed largely to the scientific movement of 1840–1860. He was born in 1813, and finished his medical studies in 1836; was appointed Professor of Physiology in Strasburg in 1837, to that of External Pathology in Montpellier in 1840, and to that of Clinical Surgery in 1851. In 1859 he took the Chair of Operative Medicine, which he held until his death.

——M. LETIÉVANT, Surgeon-Major of l'Hôtel-Dieu, in Lyons, and Adjunct Professor to the Faculté de Médecine, whose death is just announced, was a surgeon of great merit, and was well known by his writings, his principal work being on *Nerve Sections*. He was the first surgeon in Lyons to use the antiseptic method.

NOTES AND QUERIES.

BIDDING FOR STUDENTS.

To the Editor of THE MEDICAL NEWS.

SIR: In your issue of July 19, under the head of "Bidding for Students," you comment editorially on the "practice of a Baltimore medical college," to which your attention has been several times called. The Faculty of Physic of the University of Maryland has been "a Baltimore medical college" for more than three-quarters of a century, but up to the present time has not found it necessary to resort to the practices you so very properly condemn in order to fill its lecture-halls; nor is it likely that your timely and appropriate remarks should seem aimed at the University by any one familiar with its history or acquainted with its Faculty. Nevertheless, for the credit of the University among those at a distance, and in the interest of simple justice, we beg leave to say that we are not guilty of the practices animadverted upon by you in your editorial of July 19, and that we do not aim to increase the incumbrances of a "country overrun with half-educated doctors who are a reproach to the profession, and a danger to the community." I have the honor to be,

Sincerely yours,

J. EDWIN MICHAEL, M.D.,
Chairman of the Pub. Com.,
University of Maryland Medical School.

BALTIMORE, July 19, 1884.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 22 TO JULY 28, 1884.

WRIGHT, J. P., *Major and Surgeon.*—Granted leave of absence for one month, on surgeon's certificate of disability.—*Par. 3, S. O. 89, Headquarters Department of Texas*, July 17, 1884.

MCELDEREY, HENRY, *Captain and Assistant Surgeon.*—So much of Par. 12, S. O. 165, A. G. O., July 16, 1884, as assigned him to duty in Department of the East, is revoked, and he is ordered to report in person to the Surgeon-General of the Army for duty in connection with World's Industrial and Cotton Centennial Exposition, at New Orleans, La.—*Par. 12, S. O. 173, A. G. O.*, July 25, 1884.

FINLEY, J. A., *Captain and Assistant Surgeon.*—Granted leave of absence for one month, with permission to apply for one month extension; to take effect about September 1, 1884.—*Par. 2, S. O. 91, Headquarters Department of Texas* July 22, 1884.

REED, WALTER, *Captain and Assistant Surgeon.*—Relieved from duty at Fort Sidney, Nebraska, and ordered for duty as Post Surgeon at Fort Robinson, Nebraska, relieving Assistant Surgeon Henry McElderey, U. S. A.—*Par. 2, S. O. 62, Headquarters Department of the Platte*, July 22, 1884.

BENHAM, R. B., *First Lieutenant and Assistant Surgeon.*—Assigned to duty at Fort Brown, Texas.—*Par. 1, S. O. 90, Headquarters Department of Texas*, July 19, 1884.

ORIGINAL LECTURES.

VERSIONS AND FLEXIONS OF THE UNIMPREGNATED UTERUS.

A Course of Lectures delivered before the Boerhaavian Society.

BY ELY VAN DE WARKER, M.D.,

OF SYRACUSE, N. Y.; FELLOW OF THE AMERICAN GYNECOLOGICAL SOCIETY.

LECTURE I.

ETIOLOGY.

CONFUSION, which grows more perplexing as gynecology advances, so surrounds the subject of versions and flexions of the uterus, as conditions demanding correction, that it is nearly impossible to reconcile the assertion on one hand, with the general denial on the other that defines the two schools of uterine pathology. I believe that in these lectures we will better serve the cause of sound teaching by ignoring these differences, and give to the facts—both of pathology and etiology—of the subject a careful analysis, and thus lay out a secure groundwork for the more difficult study of symptoms which will follow. In this way we shall know the relations of these lesions of form and position to what I may call the paradox of symptoms.

A glance at the various etiological groups will show that the causes range through nearly the whole field of morbid gynecological conditions. I divide these causes into five great groups:

A. Causes existing in the uterus.

B. Causes existing in pelvic inflammatory conditions.

C. Causes due to non-inflammatory pelvic conditions.

D. The condition of near parts as a cause.

E. Systemic causes.

The first group (A) is of the first importance. To simplify its study, I divide it as follows:

a. Developmental conditions of the uterus.

b. Causes due to defective uterine involution.

c. Causes existing in inflammatory and other conditions of the uterus due to parturition.

d. Non-parturient inflammatory and other conditions existing as causes.

e. Causes due to uterine new growths.

a. There can be no doubt that many errors in the period of uterine development tend to the production of versions and flexions of the organ. There are no reasons why these errors should not be assigned to the very earliest stages of uterine growth. But there has developed a thoughtless habit among gynecologists to apply the term "congenital" to those flexions of the uterus which evidently have their origin in early life. When we reflect that in infantile life the uterus consists of a neck with an undeveloped body and fundus attached; that there is no proper separation of the cavities of the neck and rudimentary body, but that it is one cavity with the *arbor vitæ* extending throughout; and that the organ continues to maintain this relative proportion between the body and neck until the sixth or eighth year of life, we have good reasons for rejecting the theory of connate flexions. Dr. Hagermann, in an elaborately illustrated monograph, clearly proves the difficulty of such an origin for flexions of the uterus.

In practice, we observe a large number of flexions of the organ in young women, in which the cervix, and usually the whole uterus, are small and exceedingly mobile. To this group, C. Mayer assigns as a cause the atrophy of the uterus in childhood. This is undoubtedly the cause if we substitute for the term atrophy, the term arrested development, for we cannot conceive of atrophy in an organ not yet developed. E. Martin also takes this ground. Virchow has expressed the opinion, from appearances observed in post-mortem sections, that this group of uterine flexions, is often caused by an unequal development of the lateral ligaments of the uterus, thus tending to draw the organ forwards, and toward the shortened side. Numerous authors take the ground of congenital flexions without defining very specifically what they mean. Meissner, Boivin and Dugès, Kiwisch, Flamm, Velpeau, Sommer, Picard, West, Jobert, Cazeaux, and Tilt (Hueter) take this view. Bennet describes an anteflexion of the uterus in which there is found no morbid condition of the cervix, either as to size or position, and which he explains as "the result of the congenital exaggeration of the natural anterior curve of the uterus." Comment upon such an explanation is not necessary. The latter author explains the etiology of latero-version, when not caused by adhesions, by "congenital" causes; excepting, however, a left to right position, which is often normal. In this latter opinion Bennet has the support of Huguier. In this connection, the opinion of such a careful observer as M. Goupil demands some comment. In the examination of the bodies of twenty-five infants at the Maternité, still-born, or dead within the first fortnight, he observed nineteen cases of lateral, right or left, versions and flexions, with double lateroflexions and a retroflexion in five others, leaving only one observation in which the uterus was straight.[1] In all these cases M. Corain proved that the round and ovarian ligaments were shorter on the side of the uterine inclination than on the opposite. This difference in length between the ligaments he explains by the position of the rectum and the distention of the sigmoid flexure with meconium; thus, when right lateral version was observed, the rectum was to the left, and in the opposite displacements to the right. In two of the twenty-five cases in which sinistro-version was noticed with the rectum also to the left, the exception was explained partly by press-

[1] The following note by Bernutz and Goupil is of bibliographic interest: Aran (Archives générales de médecine, 1858, 5th séries, iii. 321) a parfaitement étudié cette disproportion des deux ligaments ronds et ovariens, dont il rapporte la première étude à Tiedemann, et qui avait été également signalée par M. Pichard. (Thèse, Paris, 1852, No. 76, p. 79), op. cit., p. 537.

ure of the sigmoid flexure and partly by the difference in the points of the emergence of the umbilical arteries, which turned the face of the uterus to the side opposite to the version.[1]

There are several reasons why the observations of Goupil and Corain should be given scant inductive value; first, they prove too much. They prove that lateral flexions and versions chiefly, but all forms in the aggregate, are the rule, and the straight, or so-called normal position and form, the exception. Secondly, the uterus during the period named is not acted upon by intrapelvic forces, but is one of the abdominal viscera, and exposed to the movements and pressure of the neighboring parts; and lastly, these authors are applying to a rudimentary organ the same laws of pathology that we are accustomed to apply to the developed uterus. One word will serve to illustrate this. Inequality being the law in the development of the uterine ligaments, it becomes the rare exception to find this lack of uniformity in adult life. The same error of induction exists in the assertion of Kiwisch and Manuel, that meteorism is the cause of congenital flexions.

Confining the etiological movement to the earliest period of uterine evolution, what are the forces which tend to produce pathological varieties of position and form? This question is not difficult to answer. Broadly, all the numerous forces which tend to arrest, retard, or pervert nutrition—more specifically, the diseases of assimilation and nutrition—the diatheses. Unhygienic conditions of food, air, and exercise; all the errors of moral and social environment which tend to sexual precocity, and thus interfere with the consecutive nutrition of all the parts.

There is marked clinical confirmation of this. The feature which is rarely absent in a case of developmental version or flexion is a defect in the size of the uterus, either of the whole organ or of a part of it, and which points to the arrested, or heteroclitic, nutrition of the part; further, these cases are usually associated with incurable sterility. The foregoing render the assumption a reasonable one that this group of flexions has its origin at the period of uterine evolution and not at the fœtal period.

One class of developmental flexions often met with requires a few words. In the instance of a short vagina and a uterine cervix more slender and longer than usual, the vaginal portion of the uterus takes the short anterior curve of the lower part of the vagina, or of the perineum. The result is an anteflexion of the neck. Cases have been observed in which, while the vagina seemed of the usual capacity, the uterus was of diminished size, and rested permanently upon the floor of the pelvis. Martin has observed retroversion or flexions caused by defective development of the posterior wall.

b. Versions and flexions of the uterus due to defective involution.

In tracing the etiological conditions of versions and flexions closely in the parturient period, we must have regard to the fact that anteversion, or flexion, in a recently delivered uterus, is a normal position. Kiwisch alluded to this important fact first, and since then several observers (Hueter, Martin, Scanzoni) have explained the phenomenon. The enlarged uterus being in the cavity of the abdomen, the vertebral column defines the line of deflection of the organ; to fall backwards is not possible. If, under these circumstances, any cause should interfere with the completion of the involution process, the anteversion or flexion might be made permanent (Kiwisch). From this cause, however, retroflexion is more frequently met with than the opposite form of displacement (Martin, Hueter, Säxinger). The reason assigned is, that after delivery the round ligaments are relaxed, and no opposing force exists to the retroversion of the hypertrophied fundus. Klob has called attention to the fact that the contraction of the round ligaments can never wholly raise the organ. Martin seeks a cause of the puerperal tendency to flexions in the fact that the form of the uterus at this period is the inverse of the infantile organ; in the latter the cervix exists with the body at the minimum; in the former the fundus and body are enlarged, while the cervix remains at less than the *ante-partum* size. He states further, that for about nine days after delivery the uterus may be felt anterior to the cervix, and after that interval posterior to it (Beigel). To this arrest of the puerperal involution process, Dr. Henry Bennet attributes the increased size of the uterus in childbearing women, rather than to inflammation. Lesions of the cervix due to parturition seem to take a large share in this cause.

In this relation the effects of abortions must not be overlooked. Retroflexions especially may be so traced (Kiwisch, Arneth, Picard, Virchow, Scanzoni, Säxinger, Hueter). Injury to the connective-tissue stroma (Rokitansky), and the more lingering character of the retrograde metamorphosis (Scanzoni) after this accident, and which Beigel believes to be a prime cause of the great excess of acquired flexions among childbearing women. Among the poorer classes the same care against exertion and improper diet is not exercised after abortion as after a labor at term. The increased volume of the uterus, and the pressure of the abdominal contents in the relaxed state of the supports of the organ, cause the uterus to leave its normal position and become retroflexed. A state of previous flexion undoubtedly tends to abortion in the pregnant woman, and the two causes may become mutually intensive.

Repeated gestation has a cumulative effect upon the amount and character of the subinvolution. Meadows advanced this theory, and cites Oldham, Tilt, Bennet, West, Duncan, and others. Among 666 cases of versions and flexions observed in unimpregnated women by Martin, 395 cases had their origin in faults of evolution. Since in sterile women anteflexion is the rule, and the opposite form found in about forty per cent. excess among childbearing women, it is usual to find that arrested involution is the main factor in the last-named displacement (Heywood, Smith, Bernutz, Goupil).

The tendency of injuries to the cervix during labor to retard or arrest the retrograde movement to a normal size appears to be due, first, to the impeded circulation and irritative hyperæmia arising from a contiguous

[1] Orth reported to the Berlin Obstetrical Society (March 7, 1875) a case of anteflexion so exceptional that I give it in the original. A child of two years. The broad ligaments are equal; the fundus easily elevatable. As cause of the anteflexion, two abnormal folds appear in the recto-uterine excavation, which arise in the neighborhood of the internal os and coalesce by means of a broad band. They steady the cervix uteri in such a manner as to allow only the fundus to incline forwards when the bladder is emptied.—*Beitraege zur Geburtshuelfe u. Gynaek.*, Bd. iv. S. 15.

focus of inflammation; and secondly, to the extension of inflammation as a result of anatomical continuity of tissue. Owing to the peculiar character of the uterine mural circulation, retarded circulation or hyperæmia may be confined within restricted areas, hence an injury to the posterior part of the cervix might lead to an arrested involution of the posterior uterine wall, with primarily a retroversion degenerating into a retroflexion as a secondary result. Relaxation of the uterus at the puerperal period gives rise to a softened condition of the parenchyma, resulting in flexion and catarrh of the organ. From such a state Klob holds that ante-is more often produced than retroflexion, due to an excess in bulk of the posterior over the anterior wall.

Arrest of the retrograde metamorphosis of the uterus affects the fundus and body of the organ rather than the neck (Hewitt); hence the body, not having support equal to the degree of hypertrophy, bends backwards.

From the softened condition of the parenchyma of the uterus after delivery, it is reasonable to expect that many mechanical causes will operate in the production of versions and flexions. In this condition, prolonged dorsal decubitis has been known to cause retroflexion (Martin, Sommer). Leaving the bed too soon after delivery has been noted by numerous authors as a cause of flexion (Kiwisch, Rigby, Moir, Martin, Säxinger, Hodge, Meissner); also bodily exertion or muscular efforts, such as laboring women are obliged to make, have been regarded as a potent cause of flexion (Lackner, Brünninghauser). From the first cause Scanzoni states that he has found it existing in the proportion of thirty-two in seventy-two cases.

Picard has traced cases of flexion to menstruation coming on prematurely, and causing a suspension of lactation, and hence an arrest of involution. Numerous authors have mentioned the causation of flexions in mothers neglecting to nurse their children (Martin, Picard). The mammary gland when excited by nursing, has undoubtedly a most active influence in promoting contraction of the uterus in the early periods after parturition, and thus acting as a physiological factor in normal involution. Among 54 women suffering from flexions, noted by Scanzoni, there were 196 children, only 57 of whom were nursed. It is among this class of women that we should look for the action of defective nutrition, so much insisted on by Martin as a cause of imperfect involution of the uterus. This imperfect general nutrition may be due to malassimilation of food, to the action of disturbing mental causes, to a depressed vitality, the result of frequent abortions or rapid childbearing, or, as is frequently the case, to a scanty supply of proper food, from either the injudicious orders of physicians and nurses shortly after confinement, or to the poverty of the woman. Martin mentions that many of the women in whom he observed the action of these causes were excessively thin.

Martin defines several varieties of versions and flexions intimately connected with the puerperal condition, and based upon the theory of hypertrophy of limited portions of the uterine wall, the result of arrested involution within the areas of hypertrophy. The inference is not a true one, however, that this limited subinvolution is always the result of a morbid process. Dr. Hagermann, of Hanover, states that involution of the uterus after labor does not take place in all parts of the organ with like rapidity, but takes more time at the placental site. Assuming that the rate of the retrograde changes is alike for all portions of the body of the organ, the inference is proper that the change is a longer time taking place in the thicker portions of the uterine wall, such as most observers admit to be the condition of the wall of the organ at the point of placental attachment.

Martin describes the following varieties:

1. Anteversion and flexion, in consequence of lengthening of the posterior uterine wall and defective involution of the placental site during the puerperal state and after.

From this cause there are two groups:

a. Recent anteversions and flexions.

β. Chronic anteversions and flexions.

Under this general head, Martin states that he has verified this etiological condition in 28 cases of living parturient women, and in 2 cases by post-mortem examination. The remote cause of this circumscribed subinvolution without regard to the situation of the placenta, is most frequently a metritis which may have had its origin during the pregnancy, at the time of the delivery, at the lying-in, or from indulging in too early sexual intercourse.

a. Recent (acute) anteversion and flexion in consequence of delayed involution of the posterior wall of the uterus when the site of the placenta. The author analyzes 55 cases, the majority being between the eighteenth and thirty-first years of age—the most active period of the sexual life. Of these, 28 were observed in primiparæ, 10 in the second confinement, 9 in the third, 2 in the fourth, 4 in the sixth, and 1 each in the seventh and eighth labors. Seven of the cases were abortions. The range in time after delivery extends from the fourth to the forty-second day. Of these parturient women, 20 were unable to suckle their children, and 25 stated that coitus was consummated in less than six weeks after labor. A large proportion of the cases were connected with endometritis, or kolpitis; a high degree of anæmia was frequently observed.

β. Chronic anteversion or flexion in consequence of defective involution of the posterior uterine wall, when the site of the placenta.

In this group 86 cases were observed. The duration of the cases, when observed, ranges from nine weeks to twenty-one years: all counting their sickness from the last labor. Over one-third were primiparæ, and over four-fifths did not exceed the fourth confinement. More than fifty per cent. of the cases was observed between the ages of twenty and thirty years. The remote etiological relations were essentially the same as in the first group (*a*).

2. Retroversion or flexion of the uterus in consequence of lengthening and thickening of the anterior uterine wall when it is the placental seat.

Of this division, it is essential to their causation that the placentæ have their site on the anterior wall, and not at the fundus, with part on the anterior or part on the posterior wall. Martin comes to the same conclusion with Rokitansky, Klob, and others, that in these instances of partial restitution of the organ, the submucous connective tissue is reconstructed in a faulty manner, and thus disposes the organ to version or flexion.

a. Recent (frische) retroversion and flexion, within eight weeks after labor.

b. Chronic retroversions and flexions.

a. Of the group of recent cases Martin analyzes 49. About twenty-eight years of age is the period of greatest frequency. The time during the parturient period in which the error of form or position was discovered was in 16 in the second week, 10 in the third, the remaining cases being distributed about equally in the weekly intervals up to the eighth week. In 14 cases the last preceding birth had been either premature or an abortion.

b. Chronic retroversions and flexions of this group were observed to the number of 205 cases. Abortion occurred in the history of one-fourth of the cases. In nearly 25 per cent. the cases were primiparæ, and in 85 per cent. the number of previous births did not exceed the fourth. The largest proportion of the cases observed, 61 per cent., occurred in the decade between 25 and 35 years, showing the potent etiological conditions existing in frequent labors or abortions. The majority of the cases were connected with impaired nutrition.

3. The following causes may be regarded as remotely affecting the restitution of the uterus after delivery, or as setting up morbid processes in the organ, which tend immediately to the production of versions or flexions. Partial spasm of the uterus after delivery, or adherent placenta (Siebald). Irregular labor-pain, tetanus of the uterus (Mende). Absence of uniformity of uterine contraction; injudicious drawing on the cord; shortness of the cord (Mende, C. Mayer); or, that flexions may be caused by cramp (Bauer).

c. Causes existing in inflammatory and other conditions due to parturition.

In the child-bearing woman it is difficult to isolate inflammatory processes due to parturition from those which may arise from other causes. So important a factor in the production of uterine disease is parturition and its attendant conditions, that it deserves separate consideration. One important effect of inflammatory action has been touched upon in the arrest or retardation of the involution process (*b*). There is left for us to consider those more evident inflammatory post-partum conditions.

A cause which leads to the speedy development of flexions is the relaxation of the mass of pelvic tissue due to intense inflammatory processes. Softening, as a primary result of acute inflammation, must precede all other etiological antecedents of flexions (Thudichum).

Interstitial hypertrophy and general or partial corporeal indurations must, from the nature of things, be secondary conditions. Inflammatory softening having occurred, two conditions develop flexions: pressure of the superincumbent abdominal viscera, and the gravitation of the uterus itself. It is probable that only in this state of the organ can Dr. John Williams's idea of flexion from gravitation be true. Its operation in any other condition of the uterus may be ignored. Inflammatory hypertrophy may be general, or corporeal, or cervical. In the former retroversion is the more common result; Bennet says anteversion. In hypertrophy of the cervix, anteflexion of the neck usually results. Dr. Meadows says "that chronic metritis and so-called hypertrophy tend, sooner or later, to the production, first, of retroversion, and finally of retroflexion." We may, however, believe with Beigel that a direct etiological condition consists of tissue alterations at the inner os, and enlargement of the fundus and body, in which case retroflexion could be a necessary result without a preliminary retroversion. With this inflammatory tissue-softening at either the inner os or in the body of the uterus, it is not remarkable that flexions result through the strong action of the abdominal muscles, as in lifting, springing, straining, coughing, sneezing, vomiting, or in difficult defecation (Rigby, Arneth, C. Mayer, Kiwisch, Sommer, Rockwitz, Moir, Hueter). Thickening of a wall of the uterus after delivery, subsequently followed in the healing process by retraction or atrophy of the affected side may act as a cause (Boivin and Dugès, Meissner). Martin found in twenty-eight cases of flexion an inflammatory post-partum thickening of the cervix. Post-partum engorgement and hypertrophy is a most frequent cause of versions due to the increased weight of the uterus (Henry Bennet, Boivin and Dugès, Lisfranc). Excessive vomiting under these conditions has been observed as causing flexions (Conway, Edwards). The inflammation due to obstetric operations frequently terminates in flexions of the uterus. The dorsal position, long maintained after delivery, particularly when the binder is firmly applied over the lower bowels, promotes retroversion or flexion (Martin). Premature exertion on the part of the lying-in woman while the uterus is normally undergoing the restitution process, and without necessarily exciting inflammation, but as the simple result of a mechanical force acting on a softened uterus may cause or predispose to version or retroflexion.

d. Causes due to inflammatory and other conditions not parturient. Much difference of opinion exists as to the possibility of a traumatic, or, what is nearly the same thing, an acute flexion. Kiwisch was the first (Hueter) to demonstrate that the normal uterus, taken from the dead subject, could not be given a flexed form at will, since the firm tissue, the considerable thickness, and slight length of the organ, with its marked resilience, resist such a change in form. Dr. Squarey assumes that traumatic flexions are due to the rupture of uterine fibres in women previously healthy; tissue-changes occurring at the seat of the injury being due to traumatism and not antecedent changes. Dr. Bantock, commenting on this theory of Dr. Squarey, says the curvature would not occur on the side opposite to the injury, except temporarily from swelling of the ruptured fibres, but that the true flexion would be found later at the seat of the injury, from atrophy of the injured tissues. The weight of authority is against any such view. Beigel does not admit the occurrence of so-called acute flexions, except as the result of previously existing uterine disease, as shown by the presence of symptoms referable to the uterus. Scanzoni and Rokitansky believe that tissue-changes, impairing the normal resilience of tissue, and especially the theory of the latter author of the destruction of the submucous connective-tissue layer,[1] exist as a preliminary to flexions.

[1] German authority upon the theory of Rokitansky is of considerable interest. Dr. Ludwig Joseph concludes an elaborate paper, Beiträge zur Etiologie der Uterusflexionen, in Beiträge zur Geburtshülfe und Gynäkologie, Bd. ii. p. 133, in the following emphatic words of disapproval: "Rokitansky's theory of the normal structure of the uterus and the origin of flexions is untenable, since the anatomical basis on which it rests does not exist."

Hueter simply admits that with these submucous connective-tissue changes at the inner os, strong muscular effort, particularly of the abdominal muscles, may increase the angle of flexion. Hewitt admits a modified acute flexion brought on by muscular effort during menstruation, and cites a case. West and Sommer hold, with Squarey, the idea of acute primary flexions; but we may safely exclude this from among etiological conditions except such as exist as a result of tissue-changes, and which are only fully realized in the chronic form of flexions.

The catarrhal inflammation of the uterine cavity, either of the neck or body, owing to the changes induced in the mucous membrane and contiguous layers, is a constant source of versions or flexions. So commonly is this inflammation present that it is rare indeed to find a childbearing woman suffering from a version or flexion in whom evidence of endometritis is not found. We have but to recall the obliteration of the internal os, the thickening and tenderness of the walls, the hemorrhagic and tender mucous lining of the fundus as the result of a chronic corporeal endometritis, in order to realize how readily these conditions drift into the necessary antecedents of versions or flexions. Papillary hypertrophy (so-called granular erosion) of the os, acting by the extension of the inflammatory process, in which it has its origin, to contiguous parts, and thus invading the cavity of the cervix, must be given causative value. When retroversion remains after the cure of erosion (Bennett), it is evidence that inflammation is yet lurking in the cavity of the cervix. The endometritic inflammatory conditions often taking place from deranged or arrested menstruation by taking cold, can also lead to those tissue-changes which result in flexions or versions. Cases of flexion which seemed to be traceable to these sudden outbursts of inflammation of the endometrium, led Martin to the idea that these flexions were often caused by rheumatism of the organ, from taking cold.

Specific inflammation must be regarded as a factor in the production of versions or flexions. It is rare to meet with a woman who has been infected with a blennorrhœa that is free from these errors of form or position. Profuse menstruation, or metrorrhagia, aside from their causative relation, may, by the ramollescence of uterine tissue, result in these displacements. For the same reasons, dysmenorrhœa, either congestive or obstructive, may, by inducing, first, softening of tissue, second, inflammatory congestion and hypertrophy, result in flexion. Injury to the cervix and to the cavity of the cervix by inflammation in near parts as a primary, and from atrophy, or cicatricial shrinking of the injured point as a secondary cause, has an important bearing. The latter cause, when acting on a point near the inner os, must almost inevitably result in flexion.

Atrophy of the uterine muscular substance, especially that form which follows puerperal involution (Klob), needs but the operation of an exciting cause to develop a flexion of the organ. This form occurring at an early period of childbearing life, may produce a serious form of the displacement. Marastic atrophy, taking place generally at a later period of life, is of less consequence in a surgical point of view, although equally potent as a cause of flexion. In aged women with a relaxation of the uterus, the pressure of the intestines upon the fundus of the uterus causes an anteflexion (Klob). Rokitansky describes a peculiarly developed transverse vein in women who have borne many children, which passes through the anterior part of the cervix at about the inner os, and which, by developing its lumen at the expense of the resistance and solidity of the uterine wall at that point, permits the organ to anteflex. Klob mentions having seen these veins a line and a half in diameter. Cases of flexion have been traced to elongation of the uricular glands, and which, by growing into the submucous layer at the region of the internal os, materially weakens the organ, and thus permits the development of flexion. An exuberant production of the ovula Nabothi, and by their enlargement causing an atrophy of the uterine tissue, may tend to flex the uterus in the same way; or, by subsequently bursting, develop a loose, reticular structure, which renders it impossible for the uterus to hold its normal form (Rokitansky, Hueter, Klob).

e. Versions and flexions due to morbid uterine growths. Various morbid products developed in the uterine wall tend to produce versions or flexions. It may so act in two ways: first, by dragging the uterus toward the side of the greatest gravity—a version resulting; or, secondly, by inducing an hypertrophy of the wall involved in the direction of its long axis, and therefore inducing an approach of the fundus and cervix toward the shortest side—thus causing a flexion. The situation of the morbid growth in the uterine wall when high or toward the fundus, may retrovert or antevert the organ; when near the vaginal junction, upon the same side, it may force the uterus to the opposite side. The law seems to be: that for small fibroids—the size of a walnut—near the fundus, version occurs toward the side involved, as the result of gravity; when at the supravaginal cervix, anteflexion results toward the opposite side; from the pressure of the growths upon the near parts. Hueter expresses the law of version or flexions from this cause by a diagram in which a line intersecting the centre of gravity of the uterus, midway between the fundus and os externum, is drawn perpendicular to the horizon. Tumors situated laterally near the fundus, in either wall, anteflex the uterus, and when developed in the lower part or middle of the posterior wall, induce the opposite form of displacement. When the growth becomes large enough to impinge upon the brim of the pelvis, it acts as a displacing force, forcing the uterus in a direction opposite to its seat of development. Kiwisch has observed lateral flexions or torsions from the presence of uterine fibroids following a somewhat similar law of displacement. Intrauterine polypi, when of small size, produce, oftentimes, a retroversion similar to that caused physiologically by a pregnancy under the third month. When these growths are pedicular within the cervical cavity, anteversion or flexion is generally the result. When of sufficient size to force the fundus uteri above the brim of the small pelvis, versions or flexions backwards, caused by the earlier stages of growth, disappear, and the uterus becomes anteverted or anteflexed (Boivin and Dugès, Kiwisch, Velpeau, Sommer, C. Mayer, Rockwitz, Scanzoni, Hodge Sims, Säxinger, Hueter, Gusserow).

B. Causes existing in pelvic inflammatory conditions.

a. Versions and flexions due to adhesions of the uterus to near parts.

b. Versions and flexions caused by inflammatory exudations.

c. Versions and flexions caused by cicatrization of pelvic tissue.

a. It is not a thoroughly settled point in etiology, whether, when adhesions are found coexistent with flexions of the uterus, the flexion of the organ was not a condition prior to the adhesions. Tilt and Scanzoni both concur in the belief that adhesions are often the result of prolonged misplacement. The displacement and the adhesions may, however, be the co-result of a common factor, and the two conditions mutually prolong the existence of each (Bennet, John Williams). A common form of flexion from adhesion is that in which the vaginal portion has contracted adhesion with the vagina—generally that of the posterior periphery ot the cervix to the posterior vaginal wall (Rockwitz, Velpeau). Sommer states that adhesions of this character are often the result of ulcerative processes of the uterine neck. In this situation one might readily confound the cicatricial contraction of old ulcers with simple adhesions. In this manner adhesion of the cervix may cause flexion, the body remaining unchanged in form, just as the body may become flexed while the cervix retains its normal form and position (Hueter).

According to Virchow, flexions are caused by adhesions of the uterus when the organ has not the necessary movement in the antero-posterior direction. Anteflexion is produced when the fundus uteri is so fixed that in the expansion of the bladder it cannot be moved backwards. The fundus then lies close upon the posterior wall of the bladder, and as the cervix is fixed, it follows that the thinnest point on the uterine body—that where the body and cervix unite—is the seat of flexion. That flexions are for the most part the result of partial inflammations of the peritoneum, in which the exudation is organized into connective tissue which causes firm adhesions, and which, later, causes the flexion by contraction. The ligaments of the uterus may also participate in both the inflammatory action and the subsequent contraction. Hueter makes a proper comment upon this: It cannot, indeed, be denied that a local peritonitis can develop after a flexion has been a long time in existence. Velpeau, C. Mayer, Rockwitz, DePaul, Arneth, Picard, West, Manuel, Säxinger, and Hueter, speak of peritonitis with adhesions developing after a flexion has formed. According to Kiwisch, it is especially the exudations which lie to one side of the uterus that cause the lateral flexions. In these cases Martin has noticed the connection of anteflexion with lateral version.

Martin has observed an extremely rare form of retroversion and flexion caused by shrinking of the lig. pubovesico-uterina, the result of inflammatory exudate, or from cicatricial contraction of the anterior vaginal vault. It may be observed to begin with an approach of the whole organ to the anterior wall of the pelvis (antepositio uteri). The lower anterior uterine segment is drawn forwards and fixed. Posterior to the neck the uterine body may be felt, in old-standing cases, forming a sharp angle with the vaginal portion. Of the 28 cases observed by Martin, 22 were married, of which 19 were sterile. The accident appears to be one belonging to early adult life, 19 of the cases coming under observation previous to the thirtieth year. Another variety of this form of uterine displacement is caused by traction of a ligamentum ovarii and fixation due to a small ovarian formation. In this form the uterine body forms an angle with the cervix, backwards and laterally to the side on which the diseased ovary lies. This state of affairs exists only when the ovarian cyst is small. When the tumor increases in size the uterus becomes detached from its surface. In this class the uterine body may be either retroverted or retroflexed.

A rare form of anteversion and flexion has been traced by Martin, to contraction of one or both round ligaments, and by adhesive exudation upon the anterior peritoneal surface of the uterus. The body of the organ can be felt behind the os pubis with more or less absolute fixation. The flexion is generally at an obtuse angle, and when due to the shrinkage of one lig. rotunda is placed obliquely. Thirty cases were observed. Masturbation was noticed as a remote cause. The shrinkage involving the ligaments is usually due to exudative inflammatory processes in the peritoneal covering. Abegg has verified, by a post-mortem, that a state of complete anteversion was dependent on old adhesions anteriorly, and also between the posterior uterine surface and the small intestines, the lumen of which was much narrowed.[1]

Anteversion and flexion due to shrinkage of the sacro-uterine ligaments, or to inflammatory plastic exudation upon the peritoneal covering of these parts, is a comparatively common etiological condition.

Martin observed 37 cases of anteflexion, and 18 cases of retropositio uteri from this cause in a total of 217 cases. From fixation of the lower uterine segment to the posterior pelvic wall, the organ is often in a state of retroposition, the corpus and cervix uteri both being flexed forwards. This condition is usually found early in the morbid process. Later, from the action of the rectal contents, retroposition disappears, and anteflexion is the prominent feature. Martin's pathological investigations throw considerable light on this condition. The exudation of pseudo-membrane with spots of discoloration was found upon the posterior wall of the uterine neck, and upon the peritoneal covering of the hollow of the sacrum. Schultze observed 71 cases in a total of 250. Of this number, 22 were virgins, 37 had borne children with many abortions. Schultze lays stress upon mechanical causes, as in too violent coitus, coitus with a proportionately too long penis, drawing of the Douglas folds in great efforts at defecation, instrumental deliveries. Martin regards septic poisoning, taking cold during or near the menstrual period, bathing—especially sea-bathing—as common causes of perimetritis posterior. Gonorrhœal infection is a common cause (Martin, Duncan, Bernutz). Freund has described a chronic atrophic posterior perimetritis in which inflammatory hyperplasia of the connective tissue naturally leads to shrinking of Douglas folds by absorption of the exudate. P. Müller dissents from the conclusions of Schultze—that the condition of perimetritis posterior as a cause of flexion in multiparæ is not a frequent con-

[1] Aran says: Dans l'anteflexion les lig. suspubiens sont tendus, résistants et surtout très-courts. Dans la latéroflexion, le lig. suspubiens correspondant au sous de la flexion est constamment racourci tandis que celui du coté opposé est tendu et allongé. (Leçons clinique, Maladies de l'uterus, p. 389.)

dition; that when shortening of the lig. sacro-uterina does occur, it is probably an additional complication, and that functional arrest of the sexual organs is due to the flexion and not to the complication.

b. Versions and flexions caused by inflammatory exudations (phlegmons). In this group, the error of position is due to the displacing force exerted by the inflammatory mass thrown out in the intrapelvic cellular tissue. Anteflexion with a lateral inclination is a common form of deviation of the uterus from this cause, as the Douglas pouch, or its lateral margins, is obnoxious to pelvic phlegmon or abscess. The largest of these inflammatory exudations, from often having their seat intraperitoneal, instead of intracellular, induce displacements of the uterus, the extent of which is only limited by the opposite pelvic wall. Usually, ante- or retropositio uteri is due to a traction-force in the direction of the displacement; but, in this etiological group, these errors of position are caused by a displacing force pushing from behind. This displacement of the whole organ gradually disappears on the evacuation of the abscess or resorption of the phlegmon; and version or flexion occurs from the persistence of adhesions, or shrinkage in the wall of the abscess. While adhesions and fixation are marked features in the uterine displacement, yet the adhesions in the early stage take no part in the displacement, that, seemingly, being dependent upon the crowding of the inflammatory mass. The extent to which the uterus is sometimes distorted from its natural form and position by this cause is remarkable. Duncan mentions cases in which a hard tumor was felt in the iliac fossa—an extension, apparently, of the phlegmonous mass—but which, on an examination by the sound, proved to be the uterus, which had been driven out of the small pelvis by the exudation, and carried to one side by adhesions. Bernutz has described cases of periuterine lateral phlegmons involving the lower uterine segment, in which the cervix, instead of being pushed away, is drawn into the affected cul-de-sac. In other cases recorded by this author, latero-versions, which were the most frequent of all the displacements, were observed connected with torsion of the uterus on its axis as the margin of the tumor was advanced.

c. Versions and flexions caused by cicatrization of pelvic tissue. This is a group of uterine deviations valuable only in its etiological relations. These are caused mainly by (1) the contraction of abscesses in suppurative parametritis, by (2) fistulous openings into the bladder or rectum, and by (3) contractions following the too free use of caustic applications to the vaginal vault or intravaginal cervix.

The contraction of pelvic connective tissue involved in severe cases of parametritis is sometimes extensive, but usually not to the extent of arresting the function of the uterus. The lateral margins of the recto-vaginal sac being common seats of these abscesses, lateral versions and torsions are very common results. When developed in the vesico-uterine cellular connections within the common peritoneal covering of the two organs, and finding spontaneous exit for the contents of the abscess through the bladder, subsequent contraction of the sac may develop a strong and nearly immovable anteversion. When the abscess escapes through the anterior vaginal wall, subsequent contraction of the fistulous track and opening may cause an approach of the whole uterus toward the pubes, when the entire vesico-uterine connection is involved. Cases may occur in which, while the fundus is movable, the cervix is drawn forwards by contraction of the anterior vaginal wall forcing the uterine fundus into the hollow of the sacrum. A retraction of the cervix from cicatricial contraction of the posterior vaginal cul-de-sac, may result from the persistent, free, or bungling use of caustics. In the days of free cautery, now happily past, it was not unusual to find the posterior cul-de-sac obliterated, and the posterior labium reduced to a trace, while the fundus was thrown forwards in a nearly incurable anteflexion. There seems to be no reason why the posterior cul-de-sac and uterine lip should be the seat of this destructive cautery except that from the position of the patient upon her back these parts more directly confront the operator.

Vesico- and recto-vaginal fistulæ, with the more or less extensive slough attending these accidents, cause an almost endless variety of versions, flexions, and torsions. Sloughing at the base of the bladder quite generally causes retroversion. Cases are noted in which the uterine cervix becomes incarcerated in the contraction following an extensive slough, the organ becoming almost inverted and the uterine cavity opening into the bladder. The author has closed fistulæ so complicated, in which the subsequent menstrual fluid escaped through the urethra. The numerous cases recorded by Emmet and Hayes Agnew quite generally involve distortion of the uterine position or form.

C. Causes due to non-inflammatory pelvic conditions.

a. Versions and flexions due to pelvic and other malformations.

b. Versions and flexions caused by pelvic tumors, extrauterine pregnancy, and periuterine hematocele.

a. Versions and flexions due to pelvic and other malformations. Stalz mentions having found lateral flexions in rachitic deformity of the pelvis. Boivin and Dugès mention as favoring conditions an increased curve of the sacrum backwards and an undue prominence of the sacro-vertebral angle. Excessive capaciousness of the pelvis tends to expose the uterus to the action of exciting causes (Hensley). Strong inclinations of the pelvis favor the development of anteflexions, and a capacious pelvis and slighter inclinations dispose to retroflexion (Holst). A narrow and incomplete development of the pelvis—resembling, in many respects, that of the male—observed in cases of menischesis, is often found connected with flexions of developmental origin, with which, however, it seems to hold no etiological relations, but both are co-results of common factors.

Changes in the lumbar curve induce changes in the direction of the long axis of the uterus relatively to its neighboring parts. Aveling gives the normal pelvic angle at 54°, but as the curve of the lumbar vertebræ lessens, the pelvic angle becomes debased. In the last condition the abdominal viscera, instead of being supported by the lower margins of the abdominal walls with a solid base over the os pubis, gravitate within the cavity of the pelvis and force the uterus downwards in a prolapsus, or forwards, or backwards. All exercise upon the feet exposes the pelvic viscera to a series of succussions, that intensify the action of the original cause. The lumbar curve was observed in a number of cases of

versions and flexions, by taking an impression of the back on a strip of sheet lead, and record made of the curve by drawing the outline of the lead, after being carefully removed, upon a sheet of paper. In nearly every case the deep arch normally observed at this portion of the spine was found to be more or less impaired. In the majority of these cases the general health was seriously involved, and the debased curve was explained by the weakening of all the muscular supports of the bony framework of the body. Aveling explains prolapsus of the uterus by this alteration of the pelvic angle, but when we conceive that this angle may, from this cause, be reduced to 27° or 25°, it is evident that prolapsus cannot be a more frequent result than versions or flexions. Figs 6 and 7 give a good idea of the mechanical effect of this alteration in the curvature of the lumbar vertebræ.

b. Versions and flexions caused by (1) pelvic tumors, (2) extrauterine pregnancy, and (3) periuterine hematocele. In this group versions and flexions are due to displacing forces. The list might be extended to several other conditions which are rarely noticed, such as exostosis within the pelvic cavity, and displacing forces having their origin in the abdomen. Pelvic tumors, other than uterine, hold etiological relations to versions and flexions principally when of small size. New developments in the ovaries, broad ligaments, and tubes have been noticed by Rockwitz as frequent causes. Head has found retroflexion connected with small ovarian enlargements. When ovarian cysts attain considerable size, if the uterus preserves close adhesions to the tumor, the organ is generally distorted in the direction of the growth of the cyst. When growths of this nature have invaded the abdominal cavity and the uterus has become detached from its wall, the organ may become flexed by the downward pressure of the abdominal contents; the direction of the flexion depending very much upon the form of the displacement existing at an earlier stage in the growth of the tumor. Ascites may produce flexions in the same manner, and which, theoretically, in case of impaired lumbar curve, should be anteflexion or version, and in cases in which the pelvis preserves its normal angle retroflexion should be the result. To the same class of displacing force meteorism belongs, which is mentioned by Kiwisch and Manuel as a cause of flexions. Parry has observed that extrauterine pregnancy most commonly produces an antero-lateral version with elevation of the uterus; at other times, when the vicarious uterus is developed anterior to the proper organ, retroversion has been observed.

Pelvic hematocele, like the periuterine phlegmon or pelvic abscess, may produce version by displacement. From the action of this cause the displacing force acts uncomplicated by adhesions, since these are accidental, not necessary, attendants. Adhesions may develop subsequent to the primary cause, and make the uterine displacement permanent, or shrinkage of the pelvic cellular tissue following the resorption or evacuation of the extravasated blood may lead to flexion by traction.

D. Causes due to the condition of contiguous parts.

a. Versions and flexions caused by the action of the rectum.

b. Versions and flexions caused by the action of the bladder.

c. The perineum, the vagina, and the uterine ligaments in their effect on the form and position of the uterus.

a. That versions or flexions may be caused by the action of the rectum and the various sets of muscles involved in the act of defecation there can be no doubt. Dr. John Williams has carefully studied this subject. Throwing out his theory concerning any normal relation of the fundus of the uterus to a line continuous with the anterior surface of the spinal column, with which he has needlessly complicated the subject, he is undoubtedly correct. In the act of defecation the bladder is first emptied; secondly, the rectum. By the completion of urination, both the uterine fundus and the bladder sink lower in the pelvis. In case of constipation, so common among women, straining is then made and the fundus forced still lower, and, having reached the maximum of descent, becomes fixed. The cervix in this condition is pointed nearly horizontally backwards, and being now the most movable part of the uterus, bends upon either itself or the uterine body. This process, by frequent repetition, may become the cause of permanent anteflexion. In case the uterus is in a state of slight retroversion from vesical distention, the straining effort then forces the fundus into complete retroversion, and the lowest point of descent is reached. At this stage the fundus becomes the fixed point of the uterus, the uterine body being also held by the posterior vaginal wall, while further straining effort forces down the cervix. Thus retroflexion results. The anterior vaginal wall may also take part in this process, when, by the fundus being forced deeply into the Douglas pouch, it is placed upon the stretch, and prevents further upward movement by the cervix.

Simple rectal distention from the accumulation of fecal matter, has been known to cause anteversion. Bedford records such a case. Gustav Carus refers an anteversion to the accumulation of feces in the sigmoid flexure of the colon and upper part of the rectum. Rectal distention united with the violent muscular efforts to expel the contents of the rectum, combine two of the factors of anteversion or flexion (Boivin and Dugès, Scanzoni).

b. The action of the bladder in causing versions and flexions may be regarded as a minor factor. Boivin and Dugès report a case in which distention of the bladder caused a retroversion, and regard this as a frequent cause of retroversion of the pregnant organ. After delivery, distention of the bladder may act as an exciting cause of retroversion (Protheroe Smith, Denman). Baker Browne cites Sir Charles Locock as reporting a case in which excessive distention of the bladder caused a retroversion in a young, newly married woman. Hewitt credits the bladder with more power to induce retroversion than the rectum has to cause the opposite form of displacement. The bladder, from its position, offers a certain amount of antagonism to a forward displacement of the uterus due to rectal distention.

c. The perineum, the vagina, and the uterine ligaments, may take a subordinate part in the etiology of versions and flexions. Tyler Smith believed that rupture, or impairment of the perineum was a frequent cause of retroflexion. If we regard the vagina as part of the machinery of uterine support, there is no doubt of the truth of this. As is already mentioned, the perineum,

in case of a very short vagina, often takes part in the production of developmental flexions of the cervix uteri. In very extensive lacerations of the perineum, prolapsus, when not complete, must always be associated with retroflexion or version, which gradually disappears in the erect uterus as the prolapsus reaches the third degree.

Dr. Williams has mentioned cases of retroversion due to elongation of the anterior vaginal wall. Sims also alludes to this cause. In the earlier stages of cystocele, anteversion results from the removal of the usual support of the vesico-uterine connection; but as the vaginal prolapse continues and the uterus also begins its descent, the anteversion disappears. The fundus, before the third degree of prolapsus is reached, may even occupy the cavity of the sacrum. Rectocele and prolapsus vaginæ are of doubtful etiological relation to the subject. Prolapsus of the uterus so quickly develops either primary or secondary in its relations to the vaginal vault, that any other form of uterine displacement is lost sight of.

Boivin and Dugès report a case in which anteversion was caused by an inflammatory congestion of the suprapubic ligaments, occurring at each menstrual period. The inflammation began in the left labium, and the thickened ligament could be traced to the inguinal ring. The same authors regard the utero-sacral and the suprapubic (round ligaments), while being shortened, as the result of long-standing displacement, yet this may ultimately exist with the force of a cause, and render the displacement incurable.

Klob, while giving the round ligaments but little value as a means of support of the uterine fundus, believes that they may render an extreme degree of retroflexion difficult of reposition by fixing the fundus. In this instance the line of traction of the ligaments falls below the junction of the uterine body with the uterine neck, and thus tends to double the uterus upon itself when in the third degree of retroflexion. It is evident from the experiments of Savage, on the structures supporting the uterus, that no slight degree of contraction of the round ligaments would tend to develop version or flexion of the uterus forwards.

E. General and special causes.

a. Flexions and versions caused by posture, incidental to occupation.

b. Excessive sexual indulgence and masturbation as causes of versions.

c. Impaired nutrition and other causes of a general nature, of flexions and versions.

a. The effect of posture, and especially such as is incidental to occupation, may have a marked influence upon the tendency to version or flexion of the uterus. The relation of long-maintained dorsal position to the causation of retroversion in the newly delivered woman has been already alluded to. Many of the modern industries which so largely employ women, are, without doubt, active causes of uterine malposition. This cause is also found to be combined with errors of diet, deficient food, and bad ventilation. The use of the sewing machine is regarded as a frequent cause of versions and flexions (Hewitt, Squarey). Occupations that require long standing upon the feet, such as saleswomen and mill operatives, favor the development of flexions.

b. Overindulgence in sexual intercourse is alluded to by many authors as a cause of flexions. Bennet believes that it may cause a retroflexion of the cervix, and especially if the cervix is rigid from inflammation, and the body of the organ yields to the leverage. In such a condition the cervix is thrust back in ante-, and forwards in retroversion. Routh has expressed the opinion that the uterine congestion that attends orgasm may, by too frequent repetition, become permanent, and thus lead to retroversion. While nothing can be objected to the theory involved in this, yet the examination of prostitutes fails to show that versions and flexions are more frequently met with in this class than in married women. An examination of a large number of the female members of the Oneida Community shows that these women, as a class, are remarkably free from versions and flexions.

Masturbation is frequently alluded to by German authors as a cause of uterine flexions. Martin cites this as a cause of anteflexion from shortening of the round ligaments and adhesive inflammation of their covering. Such cases of masturbation as the author has seen were attended with either versions or flexions, but nutrition was greatly impaired, and extreme nervous depression present, which may have been the more active causes of the uterine displacement.

c. Impaired nutrition, a state of the general health, called general debility and want of tone, from any cause, are regarded by Hewitt as important predisposing causes of versions or flexions. The impaired vital resistance and general arrest of nutrition that attend excessive lactation and rapid childbearing, are often found associated with flexions of the uterus in very evident etiological relations. Emmet states that mental disquietude, ill-assorted marriages, and the various means used to prevent conception are causes of flexions. Diseases of remote organs, especially such as involve the circulation, have been believed to have a bearing upon the causation of changes in uterine form and position. Sommer states that diseases of the heart, attended with obstructed circulation, cause these changes by producing relaxation of the uterine parenchyma. Wright traces such results to retarded portal circulation, which leads to a venous stasis of the uterine tissue.

From the foregoing review of the etiology of versions and flexions, it is evident that the question how these changes—one of form and the other of position of the uterus—may be brought about by nearly identical local conditions, is one of considerable interest. But that these different results of common etiological factors are not mutually interchangeable, the following figures prove beyond doubt. Ten German observers place the proportion of anteflexions at 65 per cent., and of retroflexions at 34 per cent. Emmet, who has had excellent opportunities for observation, makes the difference still greater, being 58 per cent. of the former to .17 of the latter. An examination of the statistics of many writers gives the ratio of retroversions to anteversions as three of the former to one of the latter. Now, while a common cause may in one instance produce either a backward or forward displacement of the uterus, the above figures clearly show that these are not chance results, but are produced by governing causes. Emmet's idea —that a retroflexion is a deviation from a previously existing retroversion—is one that is found running through the writings of various authors, and, to a certain

extent, is probably correct. As a preliminary to version, the uterus must possess a normal condition of stiffness and resistance (Squarey). This retards the development of flexion. It is an established pathological fact that changes in the structure of the uterus are indispensable to the existence of flexions (except such as may be caused by parametritis and displacing forces), either in the submucous connective tissue (Rokitansky), or through the parenchyma of the organ (Sommer). These changes may be the direct precedent of the flexion as the result of antecedent pathological conditions, or may supervene upon a previous state of version. The only instance in which a causative condition seems to produce either a version backwards or forwards is in the abnormally movable uterus of Savage. Here, what is anteversion at one visit may be retroversion at the next—most probably due to the direction in which the superincumbent intestines exert their pressure upon the uterus. Bernutz and Goupil have met with similar cases. Squarey tries to show that the uterus is always at right angles to whatever pelvic plane the organ may chance to be situated. Consequently, when the uterus is well up in the pelvic cavity, it is directed forwards; and when low, the fundus inclines backwards. When, therefore, the organ holds the former relation to the pelvis, the operation of a displacing cause produces anteflexion, and the same cause operating in the latter relation produces retroflexion.

ORIGINAL ARTICLES.

URÆMIC AMAUROSIS.[1]

By A. FRIEDENWALD, M.D.,

PROFESSOR OF DISEASES OF THE EYE AND EAR IN THE COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE.

If we refer to text-books on ophthalmology, we find that uræmic amaurosis has received but a passing notice. We must ascribe this to the fact that the oculist but seldom has to deal with this disease; for, while it is, on the whole, of rather infrequent occurrence, it remains almost exclusively under the observation of the general practitioner. Consulting works on general medicine, we will, however, be still more unfortunate in seeking a nearer acquaintance with the separate features of the disease, for it generally forms but one of the group of symptoms which threaten such danger to life, that when the patient recovers, they are but remembered as the terrors of the storm that has passed.

While it has long been recognized that transient loss of vision is occasionally observed among the other symptoms of uræmic intoxication, pathology still owes us a satisfactory explanation as to exactly how the eye becomes involved. It cannot be ascribed to the intensity of the intoxication, for examples are not wanting, in which the uræmic symptoms have gradually developed from the headache to convulsions and coma, sight having remained intact, while there are others in which the amaurosis appeared as the only prominent symptom, as is well illustrated by one of the cases to which I shall refer in this paper. But it is not only with regard to the uræmic amaurosis that this obscurity exists; we find it equally difficult to explain the absence of all uræmic symptoms in many cases of kidney disease, in which the urinary analysis and the very pronounced dropsy testify to the existence of grave lesions; while, on the other hand, we are sometimes suddenly confronted with very threatening uræmic manifestations, when the urine may show but a trace of albumen. Again, it is not altogether infrequent that a patient learns that he has Bright's disease after an ophthalmoscopic examination has been made, when before there was nothing to apprise him that he was the subject of so grave an affection; and still the cases greatly preponderate in which, even among the most exaggerated general symptoms, the retinal degeneration just alluded to does not appear. As another example of the great variability in the symptoms of kidney disease, I may allude to the many cases which run their whole course to the lethal end in which dropsy has not been observed. When we contemplate the many irregularities in all the other symptoms of kidney affections, we shall not wonder so much in finding the amaurosis in the one case, and absent in the many in which the symptoms of uræmia are equally or even more outspoken.

The uniform absence of ophthalmoscopic changes would permit us to ascribe the loss of vision in pure uræmic amaurosis to either the presence of poisonous material in the cerebral circulation, and to an effusion into the brain substance or in its ventricles equally well. Retinal alterations in cases of uræmia, with complete loss of vision, are to be regarded as preëxisting, the amaurosis being an additional complication. Cases of nephritic retinitis are occasionally met with, in which there is a sudden and complete amaurosis, accompanied by other uræmic symptoms. There will be no difficulty here to recognize that the intensified eye trouble is due to the uræmia, but it may not always be so readily attributed to this cause when the previously impaired vision has suddenly been changed to complete loss of sight, if the other uræmic symptoms are altogether absent, or present only in a subdued form. In connection with this class of cases particularly, it is always well to bear in mind that, in simple nephritic retinitis, complete blindness is not reached, and therefore, when absolute blindness supervenes, we are generally safe in charging uræmia with the damage done.

Before presenting my cases, I will describe the general characters of uræmic amaurosis. This anomaly of vision, like all other signs of uræmia, is characterized by the suddenness of its invasion, the loss of vision from the first, or in a very short time, being complete. The ophthalmoscopic examination will yield entirely negative results, except in those cases in which retinal degeneration preëxisted. There is no especial form of kidney disease to which the amaurosis is restricted; it occurs in all forms, although, perhaps, more frequently in those met with in pregnancy and scarlet fever. In some cases in which the uræmic symptoms appear at once in these fulminating forms, the patient having been seized with convulsions without any previous warning, and lapsing in a state of coma may awake from this condition and find his sight gone. At other times head-

[1] Read before the Baltimore Medical Association, 1884.

ache and vomiting alone may precede the amaurosis, which may be subsequently followed by convulsions and coma; on the other hand, in the cases just described, the amaurosis may be the highest point in the intensity of the case, from which the symptoms may recede. As the uræmic explosions may repeat themselves a number of times in the same case, so also may several attacks of amaurosis be observed in one patient.

During these attacks the urine is generally scanty or entirely suppressed, the chemical analysis showing almost always large quantities of albumen. Ebert[1] has called attention to the fact that sometimes the urine, which before had been loaded with albumen, was entirely free of it or showed but traces during the attack, and again revealed it as one of its constituents in appreciable quantities, when it had passed over.

I recently had the opportunity to make a similar observation in the case of a child, who was convalescing from an attack of scarlet fever, when violent headache, persistent vomiting, and œdema of the eyelids presented themselves, during which time the urine showed but a trace of albumen, which, however, greatly increased for a short time when these symptoms had subsided.

The state of the pupils in uræmic amaurosis differs very much according to the accounts of the various observers. Sometimes they are found perfectly normal, or, being somewhat dilated, promptly react to the stimulus of light. At other times they are widely dilated and refuse absolutely to respond to light. It is generally considered that the cases in which the activity of the pupils is maintained, offer the more favorable prognosis as regards the restoration of sight after the patient has recovered from the attack, although even in those cases in which the dilated pupils remained totally unaffected by light, complete return of vision has been observed.

The prognosis upon the whole when the patient does not succumb to the general effect of the poison is to be regarded as favorable. Sight may be re-established as suddenly as it had disappeared; it may also come back gradually, and, indeed, several days may elapse before full vision is regained. In some cases in which there were several attacks at short intervals, while the patient was relieved of the complete blindness, with which he had been afflicted, still vision remained permanently somewhat impaired. Simpson[2] has reported a case of a lady who had been the subject of an uræmic attack, in her fifth confinement, associated with amaurosis, of which she recovered with perfect sight; and who had a similar misfortune after the birth of her sixth child, but on this occasion sight was but partially restored. In cases of uræmic amaurosis at or after labor, complicated with hemorrhage, part of the damage to vision may be due to the loss of blood, and this may hold equally true to any permanent injury that may remain. I am in this connection reminded of a case, which came under my observation, in which a lady became blind suddenly from hemorrhage on the eighth day after her first labor, having had a severe post-partum hemorrhage immediately after the birth of her child. She gradually recovered sight, but one eye remained considerably impaired.

With regard to the frequency with which amaurosis occurs in uræmic attacks, no statistics have, as yet, been furnished. The cases are upon the whole rather rare, and this induced me to communicate the two following cases, which have come under my observation:

Case I.—Mr. D., æt. nineteen years. Dr. David Street was called to see the patient on November 21, 1883, and found him suffering from bronchitis, for which expectorants were ordered. November 22d he was much relieved, and he continued to improve till November 25th, when he complained of pains and soreness all over the body, which the doctor regarded as of rheumatic character, most marked in the muscles of the arms. For this condition acid. salicyl. gr. vijss, every three hours, was prescribed. In the afternoon of the same day (5 P.M.) total blindness suddenly ensued. November 26th he was still totally blind, and suffered from frontal headache—had taken altogether thirty-five grains of salicylic acid.[1] At 2 P.M., I was requested to see the patient in consultation. Suspecting uræmia, from the suddenness of the loss of vision, I examined the patient with that in view, and found œdema of the eyelids, slight pitting of the lower extremities, and Dr. Street subsequently found the urine loaded with albumen. Ordered one drachm of the fluid extract of jaborandi, every three hours, and wet cups in the lumbar region. The bitartrate of potash was also given in purgative doses. November 27: Sight much improved; perspiring freely; treatment continued. November 28: Sight perfect; patient feeling better; jaborandi continued in smaller doses. I did not see the patient after this time, but from notes kindly furnished me by Dr. Street I am enabled to state that, so far as sight is concerned, as well as the general condition of the patient, the improvement remained permanent, although albumen still appeared in the urine and the microscope revealed epithelial casts and red blood-corpuscles. December 5: Patient well enough to go out, feeling perfectly well, the urine, however, containing a large quantity of albumen. After this date the case passed from the observation of Dr. Street.

This case presents the interest of illustrating how through the amaurosis alone attention was drawn to the true nature of the constitutional disturbance. It is true that œdema of the eyelids, and a similar condition of the lower extremities, were also present, but it is not surprising that they had been overlooked, for it is the common experience that these conditions are only discovered when they are looked for to explain some more important symptom.

Case II.—Mrs. C. R., æt. forty years, having passed seven months of her tenth pregnancy applied for advice, September 2, 1883, in regard to a general feeling of discomfort, which had been developing during the previous few days. She complained especially about a feeling of tightness in the waist

[1] Transitorische Erblindung bei Typhus und Scharlachfieber. Berliner klin. Wochenschrift, vol. 2, 1868.

[2] Edinburgh Month. Journ. of Med. Sciences, Oct. 1852, p. 369.

[1] I have mentioned the quantity of acid taken, since Epstein has shown that the prolonged use of large doses of salicylate of soda produces albuminuria.

and abdomen. At this time her facial expression indicated kidney trouble, and her extremities were œdematous. September 3: The urine sent to me early this morning proved to be loaded with albumen. On this day, at my first visit she felt somewhat better, but during the afternoon a violent headache set in, which became greatly aggravated during the night, and from which she suffered uninterruptedly till morning, when it gradually yielded to large doses of morphia. September 5, at about 4 o'clock P.M., her headache having been greatly relieved, she noticed a dimness of vision, which within an hour culminated in total blindness. I saw her about 6 P.M., when she was suffering from great mental depression, which was probably somewhat attributable to her having been previously anxious about her vision, her mother having lost her sight, and she herself having been considerably annoyed by an irregular astigmatism. At this juncture, I apprised the husband of the great danger that was threatening, and presented the expediency of a premature labor, should convulsions set in. At midnight I was summoned and found Dr. McKnew in attendance, he having ordered chloral and some bromide for the convulsions, which just before had assailed the patient, but had passed off when I arrived. Prof. Thomas Opie was now sent for and just after he arrived another convulsion occurred, for which chloroform was administered; while the patient was under the influence of the anæsthetic it was decided that premature labor should be induced. This part of the case was most skilfully conducted by Prof. Opie by means of a Molesworth's dilator, and delivering by the feet. The operation certainly did not occupy more than half an hour. There was no return of the convulsions, and the patient made a very speedy recovery. Sight returned very gradually, and she did not regain her normal vision till September 7th. The child was born alive, and though small and very feeble for several months has developed into a very healthy-looking babe.

The amaurosis in this case served as the warning of the still further peril that was in store for her, and made it possible to extend the aid which she required, with that promptness which is essential to its success. In cases of this character, which have already gone so far as to render the patient blind, we may take it for granted that convulsions will invariably follow. And both to avoid this eventuality and to guard against permanent injury to sight, if the pernicious influence to which it is subjected be permitted to continue too long, I think it fully justifiable to terminate the pregnancy, especially at a period when the child is viable.

I have already mentioned that all forms of kidney trouble may lead to the amaurosis just described, and I would take occasion to make the suggestion, that the transitory amaurosis that has in isolated cases been observed in intermittent fever, and which has been referred to by Leber,[1] may have been caused by injuries to the kidneys that were inflicted in the congestive stage. I have been led to this opinion by the able paper which Prof. I. E. Atkinson recently read before the Clinical Society of this city, in which he described kidney disease as a complication of malarial fevers.

To summarize, I would say:

1. That when amaurosis suddenly overwhelms a patient in both eyes with no ophthalmoscopic change, uræmia should be suspected even in the absence of any other prominent uræmic symptom.

2. That uræmic amaurosis will continue only as long as the uræmia exists, and will disappear when the function of the kidney is reëstablished. When permanent injury to sight is observed, it may be due to preëxisting retinal changes, not at all uncommon in Bright's disease.

3. That the chances for a full return of sight are somewhat impaired when the patient has been the subject of recurring attacks.

4. That by exhibiting jaborandi and other means for inducing free diaphoresis and by free purgation a catastrophe may be averted in the general forms of uræmia, but when it occurs in pregnancy premature labor is the only remedy which promises safety to tho patient.

LITHOTOMY AND LITHOTRITY IN THE MEDICAL MISSIONARY SOCIETY'S HOSPITAL, CANTON, CHINA, IN 1883.

BY J. G. KERR, M.D.,
OF CANTON, CHINA.

IN THE MEDICAL NEWS for April 7, 1883, a list of lithotomy and lithotrity operations in the Medical Missionary Society's Hospital, for 1882, was published. Of the former there were forty-seven operations, with two deaths; of the latter, twenty-three operations, with one death.

I now send, in continuation, a list of the operations for 1883. The number is not so great as in the previous year, owing partly to the bad state of my own health, and partly to the excitement following the riot of the 10th of September, and the subsequent rumors of war with France.

It will be seen that all the cases operated on during the year have been successful. The only qualification to be made to this statement is in reference to lithotomy case No. 33, in which the result is uncertain, the patient having been taken away while still in a weak, but by no means hopeless condition.

Reckoning from the last fatal case of 1882, there were sixty-seven consecutive cases of successful lithotomy, or sixty-six cases, if the doubtful one, No. 33, ended fatally. The two years give for lithotrity forty-six cases, with one death.

Three females were under treatment for urinary calculus. One of them was relieved by lithotomy, and a large triangular stone weighing nearly two ounces was extracted. It was partly in the urethra, so that the staff could not be passed into the bladder. The long distention of the neck of the bladder had paralyzed the sphincter, and it is doubtful if ability to retain the urine is ever recovered. In other respects the relief of her sufferings was complete. Another patient was operated on by lithotrity, and the calculus removed at one sitting by Bigelow's aspirator. The third female was a girl, who was not in a fit state for the operation.

Lithotomy Operations in Medical Missionary Society's Hospital, Canton, China, in 1883.

Another patient had renal calculus. There was a fistulous opening in the lumbar region, resulting from abscess, brought on probably by renal obstruction. On enlarging this to remove what was supposed to be a piece of necrosed bone, a small calculus was brought away in the forceps. The kidney had been destroyed by the inflammation attending the abscess, as no urine was discharged from the fistula.

During the year, six deaths from urinary calculus, previous to operation, occurred in the hospital. From one of these the stone was removed post mortem by Dr. J. F. Wales, physician to the foreign community in Canton. It weighed six ounces, and could only be extracted whole by doing damage which in the living subject must have been fatal.

The modification which I have proposed of Bigelow's evacuating-tube has been found, on trial, to work admirably. This consists simply in curving the tube to a right angle, at a point about one-third of its length from the outer end, so that the débris, on reaching this angle, falls by force of gravity into the receiver. This shortens very materially the distance from the bladder to the point where the fragments fall, and, of course, lessens the amount carried back by the current.

THE USE OF COLLAPSIBLE METALLIC TUBES IN THE DISPENSING OF OINTMENTS IN OPHTHALMIC PRACTICE.[1]

BY CHARLES A. OLIVER, M.D.,
ONE OF THE OPHTHALMIC AND AURAL SURGEONS TO ST. MARY'S HOSPITAL, PHILADELPHIA.

THIS method was brought to the author's notice about two years ago by a suggestion from an artist-patient, and from noting its good use in connection with ointments for general skin disease. He does not in any way claim that the idea is new, but thinks that, after some personal trial, his experience with the plan is worthy of record.

The advantages are several:

First. Cleanliness. The material is enclosed in a perfectly new and clean tube, the drug thus being free from any deleterious influence by access of extraneous matter.

Second. Economy. No more ointment than is absolutely necessary will be used at each application. None can be lost by carelessness, or accident in upsetting, or from breakage, as in glass jars or earthen pots.

Third. No exposure of the drug to the atmosphere. The preparations are practically sealed, the tube always being completely filled; consequently, all of the evil effects from contact with the air are avoided.

Fourth. Readiness of application. There is no necessity for an article to apply the ointment, the tube itself serving as a quick and efficient means.

Fifth. Better regulation of amount to be used. This is obvious when we consider that any degree of pressure can be brought to bear upon the tube in forcing out certain desired quantities of the contained material.

[1] Read before the Philadelphia Ophthalmic and Aural Book-Club Association, April 21, 1884.

Sixth. Less risk and greater ease in carriage. A small cylinder closed by a tightly screwed cap, is more convenient and safer to have about the person than a box or a pot with a loose lid or top. The tube can be easily carried in a pocket, whilst no amount of ordinary pressure can burst its walls or force the cap.

The objections that have been found are:

First. In labelling. Although this has not been any worse than in the ordinary form of boxes, pots, and jars, yet many attempts have been made to obviate the difficulty experienced by the loosening of paper labels from the body of the tube and the proposed large flat caps. All of these attempts had to be resigned in favor of a wired pasteboard tag.[1]

Second. Free expulsion of the ointment. At first this seemed to present an almost insurmountable difficulty; but, by experiment with a variety of special ointments through different sized openings, the following rough rules were obtained: Vaseline and rose-water ointments, holding small percentages of drugs, as well as nearly all of the oleates, are expulsed with great facility through the ordinary opening of about one-half millimetre diameter. Stiffer ointments, and those containing a powder in any quantity, as a rule, require an increase in the size of the aperture to about two millimetres in diameter.

Third. Chemical decomposition. This is the most serious objection, and the one necessitating the entire abandonment of the method, except in cases either where drugs with no real or harmful affinity for the metals of the tubes are employed, or that they shall practically become inert by the extremely small amounts embodied in the ointments used.

Conclusion. In the dispensing of eye ointments, collapsible metallic tubes are useful by reasons of cleanliness, economy, non-exposure of the contained drug to the atmosphere, readiness and facility of application, better regulation of the amount to be used, and less risk and greater ease in carriage; whilst they are contraindicated by difficulty of expulsion of stiff ointments, and chemical change, causing either a deposition of some of the elements of the tube into the ointment, with a thinning and breakage of the tube walls, or an action upon the contained delicate substance, rendering it either useless or harmful. Consequently, at present, until some better material can be employed in the manufacture of collapsible tubes, it will be better to continue the use of wood, glass, and porcelain, to insure purity of drug and surety of action.

1507 LOCUST STREET.

[1] Mention might be made of the possible good use of a well-recommended paste, containing honey and tartaric acid amongst its ingredients, in producing the best adhesion between a paper label and a metallic tube. This was tried, but no reliance could be placed upon the results with the materials employed.

MEDICAL PROGRESS.

GASTROSTOMY.—MR. PAGE performed this operation at the Newcastle-on-Tyne Infirmary about five weeks ago. The patient was a stonemason, about forty-six years of age, and, except for being a heavy drinker,

there was nothing to point to as a cause for the symptoms of dysphagia, which came on gradually, but became very urgent about the beginning of the present year. It is nearly a month since he was admitted to the infirmary, and fully three weeks since the operation. Mr. Page made an incision through the rectus muscle on the left side, and to this the stomach was secured by wire sutures, and opened three days later, the patient in the meantime being sustained by nutrient enemata and hypodermatic injections. When the gastric fistula was fully formed, he was fed through an elastic tube, and at the present time, although he is still being fed by the tube, he has recovered some power in swallowing, and has increased in weight four pounds since the operation. At the time of the operation, he was harassed by a hectic cough, and this somewhat induced Mr. Page to make his opening through the rectus, the structure of the muscle acting in a valvular manner, and so preventing expulsion of the contents of the stomach during the act of coughing. The presence of the tube appeared to give the patient, who was able to walk about the ward, very little trouble. The case is doing well.—*Lancet*, July 12, 1884.

Amorphous Borate of Quinine.—Borate of quinine occurs as an almost crystalline powder, of an amber color, slightly distinct odor, bitter taste, but less pronounced than that of hydrochlorate of quinine. It is very soluble in water.

Finkler and Pryor have given it in capsules in doses of gr. vij to xv, repeated every half hour or hour, so as to give a maximum dose of gr. xlv in from two to four hours. It has been given in the Clinic at Bonn, in a large number of cases of tuberculosis, and in acute and chronic gastric catarrh. There were, among these cases, patients in whom the least error of diet caused vomiting. None of them vomited after taking the borate of quinine, nor did it cause pain when administered to phthisical patients who had chronic catarrh of the stomach. Besides its action on the stomach, borate of quinine may be used in these cases on account of its disinfecting action on the stomach and intestines. The daily absorption of gr. vij to xv, for weeks at a time, causes no unpleasant symptoms on the part of the digestive tract.

Patients with high fever bear the drug well. It seems to be well borne, especially when followed by a little water, wine, or cognac. The subjective troubles, especially the aural, are not so pronounced as after the ingestion of hydrochlorate of quinine. It was tried in 5 cases of typhoid fever, 1 case of septic fever, 3 cases each of pneumonia and erysipelas, and in a typical case of trigeminal neuralgia. It was shown that doses of from gr. vij to xlv always reduced the temperature.

It was observed that after the administration of the borate, there was a sudden and rapid fall of the temperature. By giving it in the afternoon, an evident effect was observed in the temperature of the next morning. By frequently taking the temperature it was ascertained that while the effect of a dose continued for quite a long period, the temperature was not sensibly affected until from two to four hours after the ingestion of the drug.—*Centralbl. für die gesam. Therap.*, May, 1884.

Rupture of the Sigmoid Flexure in New-born Children.—Zillner made post-mortem examinations of four children, who had died, within twelve or fifteen hours, of peritonitis from rupture of the sigmoid flexure. These cases are interesting from a medico-legal point of view. It was questionable if the rupture was not produced by violence in giving enemata. It seems scarcely probable that any usual violence during delivery could have caused the accident. Zillner also offers the following explanation. During the labor the mother presses upon the abdomen of the child, thus fixing the sigmoid flexure, which is filled with meconium, or else draws it down into the pelvis. Then comes a moment when the pressure on the abdomen is so strong that the sigmoid flexure comes between the lumbar vertebræ or the linea arcuata on one side, and the abdominal walls on the other, until it is compressed tightly and cannot move. The meconium can either slip away toward the descending colon, or into the rectum, slight pressure only being necessary to rupture the upper part of the flexure. Experiments seem to bear out this theory.—*Centralbl. f. klin. Med.*, July 5, 1884.

Extirpation of the Larynx.—A. Preetorius reports (*Deutsche Zeitschr. f Chir.*, Bd. xix. Hft. 6) a case in which he removed the larynx of a fifty-four year old woman for carcinomatous disease. Tracheotomy was performed fourteen days before the operation. During the operation the larynx was closed by means of Trendelenburg's condom-canula. This remained in place until the afternoon, when Michael's canula with a rubber bag was introduced through the upper aperture of the trachea, and the bag filled with a mixture of glycerin and water. The Trendelenburg's condom-canula, and Michael's with the rubber bag were used alternately for several days. The patient recovered.—*Centralbl. f. Chirurgie*, June 21, 1884.

Arrested Labor from Rigor Mortis of Fœtus.—Dr. Robert Boxall reports this interesting case, which occurred in the General Lying-in Asylum, York Road. The head would not descend, and the lower blade of the forceps was used to bring it down through the cervix. The blade was then removed, and labor terminated naturally. The fœtus was of a mottled blue color, and stiff.—*Lancet*, July 12, 1884.

Chronic Heart Disease and Pregnancy.—This is the subject of an inaugural dissertation by G. Wessner, of St. Gall, who gives the following *résumé*, after a careful review of the literature of the subject:

1. There is no specific physiological hypertrophy of pregnancy. The heart of the pregnant woman only obeys the general law that the mass of the cardiac muscle increases with that of the body.

2. Other grounds for believing in a physiological hypertrophy are faulty, and cannot be brought into pathological relation.

3. The conditional hypertrophy of the heart, of pregnancy, caused by increased body-weight, is so slight that it can only be considered as a danger in very severe heart trouble.

4. The causes of the unfavorable influence of pregnancy on heart troubles, lie not so much in the in-

creased cardiac activity, on account of the pregnancy, or the pressure suddenly removed by labor, and the high position of the diaphragm, as in the psychical and physical fatigue of labor, which reacts on the heart.

5. But, as statistics show, these are endured in by far the greater number of cases, without especial damage. It seldom occurs that severe heart trouble is specifically due to pregnancy, but it more usually happens that we have to do with very severe heart disease as a secondary complication.

6. As malignant endocarditis occurs especially in the course of old heart diseases, so it also seems to occur after labor, as septic poisoning.

7. The prognosis is considerably better for both mother and child, if it exists from the beginning.

8. The treatment is symptomatic, not the performance of premature delivery, but hastening labor if necessary.

Of this thesis, Kriworotow, the translator, makes the following remarks: Wessner has drawn these conclusions from a collection of 77 cases in German and other literature, which showed various forms of heart trouble at birth. In these cases 42.9 per cent. had no, or only slight symptoms; 19.5 per cent. had severe symptoms; and 37.6 per cent. died. But Wessner, after critical examination of these cases, very much reduces the percentage, while he considers the further complications.

The independently worked up material gives striking and interesting results: Of 25 women with heart disease, which were observed in the Clinic at Berne, there were 93 labors and only 1, a primipara, died. She was twenty-eight years old, had mitral insufficiency and double pneumonia, and during the fourteen days preceding labor had extensive œdema of the lower limbs. The child was born dead. At the autopsy of the mother, who died on the day of labor, the clinical diagnosis was completely verified, the kidneys being also markedly congested. The other 24 women had no especial trouble.—*Centralbl. für Gynäk.*, June 21, 1884.

Secondary Suture of the Median Nerve.—At a recent meeting of the Academy of Sciences, M. Tillaux related two cases of secondary suture of the median nerve followed by rapid restoration of the functions in the parts depending upon it. The first was a young girl who cut the front of her wrist whilst cleaning some windows in November, 1883. The wound healed without suture of the nerve being performed, and there remained complete paralysis of all the parts supplied by it. Incapable of working, the girl went to the Beaujon Hospital to seek relief. The parts supplied by the median nerve were found to be colder than on the opposite side, and of a slightly violet color. Notwithstanding the discouraging nature of the case, M. Tillaux decided to give the patient a chance. The ends of the nerve were found about a centimetre distant from one another, the central one bulbous, the peripheral atrophied. They were cut so as to present a fresh equal surface and carefully drawn together by a hair suture (*crin de Florence*). An antiseptic dressing was applied and the limb immobilized in extreme flexion. Two days after the operation sensibility began to return and increased daily. Six weeks later she left the hospital with sensibility and movement entirely restored. The other patient was a woman, who, witnessing the result in this case, begged M. Tillaux to operate upon her also, notwithstanding that the accident had occurred fourteen years before. The operation was identical, and the next day sensibility began to return, and was soon entirely restored. The physiological curiosity of these cases lies in the fact that when examined microscopically (by M. Ranvier) the portions of nerve removed exhibited no trace of cylinder-axis, and that it is difficult to explain the restoration of function by our present ideas on the subject. M. Tillaux's observations may be the starting-point of an important discovery.—*Lancet*, July 19, 1884.

Echinococcus of the Spleen.—Professor Mosler has recently written a monograph on this subject. Besides the twenty-eight cases tabulated by Niesser in 1877, Mosler has collected twenty-eight others, and from a study of the whole number he draws the following conclusions:

1. Sex seems to give no predisposition toward echinococcus of the spleen.

2. The affection is most usual between the ages of twenty and thirty years.

3. As regards symptomatology, the signs of the tumor may be so slight as to give no symptom during life. In other cases the first symptom is an intense pain after some exertion, or after labor, showing inflammation of the echinococcus cyst.

4. The diagnosis rests mainly on the physical signs, and is difficult. These tumors differ from other tumors of the spleen in their fluctuation.

5. The prognosis of solitary echinococcus of the spleen is certainly more favorable than when other organs are involved.

6. Internal treatment amounts to nothing. The sac must be opened by means of scissors, and Volkmann's method for suppurating echinococcus of the spleen followed.—*Deutsche med. Wochenschr.*, July 3, 1884.

Tracheotomy in Croup and Diphtheria.—Dr. Luening, assistant to Dr. Krönlein, has recently written a monograph on this subject, in which he has collected statistics from 1868 to 1882, including the severe epidemic in Zürich in 1881–82.

Croup and diphtheria are anatomically different, but etiologically and therapeutically one. Of 295 cases twenty per cent. got well without operation, and with a slight degree of laryngeal stenosis. Tracheotomy was performed in eighty per cent. of the cases, and thirty-nine per cent. recovered, giving fifty per cent. of recoveries with and without the operation. The operation seems to be growing in favor from year to year. In 1881 there were forty-five operations in Zürich, with forty-five per cent. of recoveries, and in 1882, up to March, there were forty-five with forty-two per cent. of recoveries.

There is no contraindication against the operation in laryngeal stenosis. It was successful in eleven out of fifty-two children under two years of age. When the child is asphyxiated, and apparently lifeless, the operation must be instantly performed, although, of course, the chances are against recovery. The operation should be performed earlier and oftener.—*Deutsche med. Wochenschr.*, July 3, 1884.

Cancer of the Pancreas.—M. Babillon, at a recent medical clinic, showed a specimen of cancer of the pancreas, taken from a patient of M. Débove. It presented a number of carcinomatous nodules, as well as a multilobar cyst seated near the inferior border. The patient died within fifteen days after his admission to the hospital. He did not vomit, but the food was simply regurgitated almost immediately after eating. There was no hæmatemesis or melæna, but there was habitual constipation and the abdomen was retracted. The epigastric region was painful and the seat of general puffiness, without appreciable nodules. The diagnosis of cancer of the stomach was made.

The autopsy showed a very large aneurismal dilation of the arch of the aorta. The left lobe of the liver extended across the epigastric region, and contained carcinomatous nodules. There was carcinoma of the stomach, near the cardia, which involved the neighboring lymphatic ganglia. As before stated, the pancreas was chiefly invaded, and contained a collection of puriform fluid.

This case is interesting from several points of view. It would seem that the aneurism of the aorta and the dilatation of the thoracic aorta which ended abruptly at the diaphragm, were perhaps caused in some way by the pressure of the carcinomatous mass upon the abdominal aorta. It is again interesting from the fact that there was no true vomiting, but almost immediate regurgitation of the food after taking it, which led to the diagnosis of cancer of the stomach, and presumably of the cardiac portion; and lastly, on account of the cystic and carcinomatous alterations of the pancreas, which should have been accompanied by glycosuria; but the urine contained no sugar.

Among the many theories which have been proposed to explain the pathogenesis of diabetes, there is one which makes the pancreas play an important part in its causation. According to this theory, which was especially advocated by Popper, and which is sustained by a certain number of anatomical facts, such as fatty degeneration with sclerosis, atropia, cancer, and obliteration of the pancreatic duct; diabetes may be explained in various ways. The sugar produced by the affected pancreas may be insufficiently elaborated, or the obstacles to the performance of the pancreatic functions cause absorption of the pancreatic ferment, which, taken up from the circulation by the liver, renders the transformation of glycogen into sugar more active. Again, the pancreatic disease, by opposing the transformation of nitrogenized materials, causes a state of inanition, and sugar, continuing to form, is not consumed by the organism (Fick and Heidenhain). Lastly, it is said that the affected pancreas, not being able to furnish, for the saponification of fats, a sufficient quantity of fatty acids to combine with the glycogen, and form the biliary acids, there is an excess of glycogen in the liver, and, consequently, the quantity of sugar formed in that organ is increased. The case above recorded seems opposed to the pancreatic theory of diabetes.—*Progrès Méd.*, July 5, 1884.

Button in the Larynx.—Schrumpf reports the case of a six months old child, which apparently got a chemise button into its larynx. Tracheotomy was performed, but the button could not be found. The child died of broncho-pneumonia on the fourth day, and the button was found against the posterior wall of the œsophagus at the level of the cricoid cartilage.—*Centralbl. f. Chirurgie*, June 21, 1884.

Intestines Adherent behind Uterus.—Mr. Lawson Tait reports the case of a woman, aged thirty-two years, who presented herself at the Birmingham Hospital early in November, 1883, complaining of constant pelvic pain dating from her last confinement, and much aggravated by the patient having "strained herself" six weeks before. On examination, the uterus was found to be somewhat fixed with a mass behind it, very tender on pressure, and clearly cystic. But for the fact that she complained of no increase of pain before or during menstruation, he should have diagnosed the case to be one of occluded and distended tube. As it was, he made no diagnosis, but advised abdominal section. This the patient readily agreed to, and he performed it on November 8th. He found a good deal of matter in the pelvis, and a coil of intestine adherent in the cul-de-sac. He undid the adhesions without much difficulty and closed the abdomen. She left the hospital on November 28th, and has been entirely free from pain since. He saw her last on July 7th, and found that she has had no return of her old symptoms, and is in perfect health.

This case is a very instructive one, for the physical signs were precisely those of pyo- or hydro-salpinx; and if it had happened that the patient had suffered much at menstruation, he certainly should have set it down as a case of one or other of those diseases. Suppose that, under this belief, he had acted as some (who have had no experience) advise, suppose he had tapped from below, he should have done no good; he would probably have made his patient worse; he might even have killed her. On the other hand, following his rule of opening the abdomen, he was able, with very little difficulty, to cure completely a condition which distressed the patient, which put her in constant risk of her life, and for which no other remedy was possible.—*Med. Times and Gaz.*, July 19, 1884.

Suprapubic Cystotomy.—Adolphe Garcin has recently published an inaugural essay on this subject. To the 106 cases recorded during the years 1881 to 1883, inclusive, he adds 10 new cases; 9 by E. Boeckel and 1 by J. Boeckel. The purpose of epicystotomy is threefold: first, for removing tumors of the bladder; secondly, for cases in which catheterism cannot be performed; and, thirdly, for the removal of calculi and foreign bodies from the bladder. In the last set of cases the mortality was about 24.4 per cent. Still, of 23 deaths, 12 occurred from pyelitis, erysipelas, etc., and 5 cases out of 11 of infiltration of urine after the operation. The majority of the cases which recovered occurred between the ages of ten and twenty years of age; for these ages the tables show 26 recoveries and only 1 death. As advantages of the operation over the perineal operations may be mentioned: the greater simplicity of the operation, the small amount of hemorrhage, the impossibility of wounding important organs, the ease with which the calculus is extracted, the avoidance of injuries from bruising, the possibility of thoroughly examining the bladder, and of keeping the wound aseptic. The single

danger of infiltration of urine and perivesical phlegmon, are also consequences of the perineal operation; besides purulent infection, secondary hemorrhage, incontinence, sterility, and persistence of a fistule, which are also consequences of the perineal operation. It is especially worth of remark, that a fistule has never resulted from an epicystotomy.

The indications for the hypogastric operation for calculi or foreign bodies are as follows: 1. Impossibility of lithotripsy on account of the hardness and large size of the calculus. 2. Calculus formation around a foreign body. 3. Encapsulation of the calculus. 4. Situation of the stone in a sac behind an hypertrophied prostate. 5. Great prostatic hypertrophy. 6. Great narrowing of the urethra, 7. Irritability of the vesical mucous membrane. 8. Anchylosis at the hip-joint. 9. Considerable renal changes. Of course, these indications are to be applied only to males.

It is scarcely necessary to say that the patient should be placed in the best possible conditions of health before the operation, and all irritation of the vesical mucous membrane should be avoided, in so far as possible. In order to render the operation easier, from f℥vj to ℥x of borated or carbolated water should be thrown into the bladder, and ballooning of the rectum be resorted to. The question as to whether the wound should be drained or completely closed up, must be determined by the surgeon in individual cases. Suture of the bladder has been used in 20 cases in the past four years, and only 2 healed by first intention. On the other hand, 7 cases died of urine-infiltration, in 5 of which the bladder was sutured. Garcin advises drainage of the bladder with strong double drainage-tubes, the outer wound being gradually closed from the upper part, by sutures. For dressing he recommends an antiseptic sponge, which acts as a siphon to the drainage-tubes. At the beginning of the second week the drainage-tubes may be generally replaced by the permanent catheter, or by repeated catheterism. By such treatment the process of recovery will generally occupy about forty-one days.

J. J. MACAVEJEV gives (*Vratsch*, Nos. 12 and 13, 1884) a *résumé* of his operations of epicystotomy. He has performed the operation eleven times, and sutured the bladder once. Of the 10 cases in which the bladder was not sutured, all were between the ages of two and seventeen years, and in the majority of the cases there were complications on the part of the urinary apparatus. 5 cases recovered in four weeks, 3 in from eight to twelve weeks; 2 cases died, 1 of erysipelas, and 1 of inanition. In his last case, Macavejev sutured the bladder with catgut, the mucous membrane not being included. An antiseptic dressing was used and the catheter removed on the seventh day. The patient was well in a month.—*Centralbl. für Chirurgie*, June 21, 1884.

MALARIAL ORCHITIS.—A. ZACCO reports a case of a man, æt. thirty-five years, previously in good health, who had an attack of orchitis on the right side, with a complicating epididymitis, without having had any venereal disease, or any affection of the urinary organs. After this the patient had intermittent fever for three months, complicated with tertian, and later with quotidian, and finally a continuous fever set in with orchitis. Every method of treatment was used without resulting favorably. But after it was discovered that the continuous fever reached its acme about noon, large doses of quinine were commenced on the fourth day, and in two days the patient was very much better. It was observed that at the height of the fever there were slight swelling and pain of the testicles, which, however, completely disappeared with the fever. Zacco believes that the orchitis was due to the direct action of the malarial poison, which had become implanted in the testicles.—*Centralbl. für klin. Med.*, July 12, 1884.

GANGRENE OF UTERINE FIBROIDS AND THE DANGERS OF PARTIAL EXTIRPATION.—MERNER (Thèse de Paris, 1884) reports the case of a woman forty-four years of age, who had a submucous myoma, as large as a child's head, situated in the anterior wall of the uterus. An operation was performed and a portion of the tumor was left behind, which caused death in fourteen days by sepsis. This case, as well as other similar cases reported, caused Merner to write up the subject. He concludes that such tumors have a tendency to suppurate and cause death in spite of the most painstaking antisepsis, and he takes the position that all methods of operating which will only partially remove the tumor are bad, and should only be used when no other method can be employed.—*Centralbl. für Gynäkol.*, July 12, 1884.

THE OPERATIVE TREATMENT OF TUBERCULOSIS.—DR. A. P. SELENKOW (*Vratch*, Nos. 16 and 17, 1884) has an article on this subject. In tuberculosis of the bones and joints the diseased bones were resected, the affected soft parts carefully removed, and an antiseptic dressing applied. In order, however, that the remaining germs should not develop, the dressing and drainage-tubes were removed in three or four days, the secretions pressed out, through drainage established by means of an elastic catheter, and a forcible injection, generally of a ten per cent. alcoholic tincture of iodine, made into the wound cavity. Closure of the wound should be treated by reopening it, and reinjection of iodine. After the superfluous iodine has run out, the drainage-tube should be replaced and a fresh dressing applied. This should be repeated every three or four days until there is no more fluid secretion. Finally the drainage-fistula closes, and a scab forms. On the first appearance of a return of the trouble the fistula must be scraped out again and sytematic syringing employed. No irritation of the wound is seen under this treatment; the vicinity of the wound must be protected from the iodine by a coating of vaseline. Selenkow has used resection in six cases in different joints, two being very extensive injuries. Both healed without the occurrence of fistules. In three of these cases iodoform was also added to the iodine, and directly applied to the fresh wound, or applied in the form of pencils. This form is highly valued by Selenkow, as the energetic action of the iodine seems to supplement the weak but lasting action of the iodoform. Iodoform is equally efficacious after the opening of scrofulous and other abscesses, though it is not to be recommended in congestive abscesses, in which the primary congestion cannot be removed, as for example in spondylitis.—*Centralbl. für Chirurg.*, July 12, 1884.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

THE CHOLERA OUTLOOK.

THE favorable cholera reports from the south of France indicate that the disease is fast disappearing from the cities of Marseilles, Toulon, and Arles, though it is gradually extending among the villages north of those places, and has crossed the Alps into some of the smaller towns of Italy. Several "sporadic" cases are said to have occurred in Paris, and one death is reported at Lyons. The total number of deaths from the disease, from its outbreak up to August 2d, is reported to be at Marseilles 1248, and at Toulon 638.

Not only has the progress of the cholera been very slow, but the mortality record shows that its fatal results have been far below those of former visitations, and leads us to hope that it may be held in check beyond the sea by continued watchfulness and the employment of the hygienic and other measures now being applied in the countries more immediately threatened with the disease.

Notwithstanding the favorable outlook, the utmost vigilance should still be exercised by those in charge of health matters in the United States—national, state, and municipal—and there should be no relaxation in the efforts being made to ward off the disease or prepare for its reception. No other disease carries with it such a widespread terror, and as its march is governed by the laws which govern travel, it would seem that its progress should be arrested by an intelligent supervision of those lines of human intercourse which would, unprotected, bring it to us; and that, with the Government's vessels patrolling our coast, with its watchful officers at every port, with our State and municipal authorities guarding the interior lines, and keeping our towns and cities clean, the progress of the disease cannot give cause for serious alarm.

PULMONARY LESIONS PRODUCED BY INHALATION OF PHTHISICAL SPUTUM AND OTHER ORGANIC SUBSTANCES.

IN Virchow's *Archiv* for June, 1884, DR. W. WARGUNIN, of St. Petersburg, publishes his investigations in this line of experimental research. After reviewing the work of Tappeiner, Klebs, Bertheau, Schottelius and others, he concluded that the tubercular nature of the primary lesions in the lungs of animals thus experimented on, was by no means clearly established by their experiments. He then sought, by following out the pathological processes in dogs from the beginning, to determine their nature.

The details of the experiments, which numbered 21, were in all respects carefully carried out. They were arranged in three categories: 1. A series of 11 dogs, in which the fresh sputum of patients suffering from well-characterized phthisis was used for inhalation, chiefly by Seigle's apparatus, but in two instances by a hand-ball apparatus; 2. A series of 3, in which the same kind of sputum, disinfected by carbolic acid and repeated boiling, was used; 3. A series of 7, consisting of 1, in which the sputum of a patient suffering from emphysema and bronchial catarrah, of 4, in which an infusion of Swiss cheese, and of 2, in which an infusion of wheat flour were employed. Two of the dogs in the first series were suffered to live, and showed no signs of illness; three of the whole number died of exhaustion, refusing all food; the rest were killed at various periods after the more or less frequent repetition of the inhalations. The three categories gave in every respect precisely the same result. The clinical picture was in all instances the same, and afforded none of the indications of a general sickness. The anatomical condition of the lungs presented macroscopic appearances exactly resembling acute miliary tuberculosis. Tuberculosis of other organs was not encountered.

Dr. Wargunin subjected all these specimens to careful microscopic examination, and he concludes, from due consideration of the clinical facts, the results, and the histology of the processes in the lungs, that in all cases the process is one and the same, and that it cannot be regarded as tuberculosis. He regards it as a lobular pneumonia, which in many respects resembles the desquamative pneumonia of Buhl. Etiologically, it is, however, to be referred to the category of pneumonia due to foreign bodies. He found that the inflammatory process which begins in the bronchioles, only secondarily affects the alveoli. The lung affection tended to complete restoration of the lung tissues when the

animals were placed under favorable hygienic conditions. Instead of destruction of the affected portions of the lung, with the formation of cavities, as he expected, he was surprised to find in two instances upon examination of dogs killed after six months, normal lungs. Koch's discovery of the tubercle bacillus, which was announced as the investigations of Dr. Wargunin were completed, appeared to establish facts wholly at variance with these results.

How could the fresh sputum of phthisical patients containing bacilli and the disinfected sputum, give rise to the same results as cheese and wheat flour? The only reply to this question lies in the assumption that even the bacilli of Koch are not specific. Wargunin does not hesitate to assert to-day that Koch's discovery requires much further corroboration; that it has thus far been worked out in too superficial a way for so important a question; and that it contains in itself much that is problematical. Without denying the parasitic nature of the infectious diseases, he insists that many things must be made clear before the etiology of tuberculosis will become so simple a matter as the discovery of the tubercle bacillus of Koch would appear to make it; in other words, that the doctrine of Koch as to the cause of tuberculosis calls forth a great number of questions which are but imperfectly or not at all answered by that doctrine in its present phase.

The wide difference between these results reached by Wargunin and those of Tappeiner, which were discussed in our issue for May 5, 1883, only goes to show how unsettled must still be regarded this great question of the nature and etiology of tuberculosis. In 18 experiments by Tappeiner in which tubercular sputum was inhaled, 17 were followed by tubercle of both lungs and pleura; in 4 there were in addition tubercular nodules in the kidneys, spleen, and liver. In one instance only was there disseminated desquamative pneumonia; while in Wargunin's 21 experiments summed up above, of which 11 were done with true tubercular sputum and 10 with indifferent substances, in all of the animals which died or were killed, being 19 out of the 21, there was found desquamative or broncho-pneumonia.

Still more striking is the difference when Wargunin's results are compared with those of Koch, as published in the second volume of the Imperial Health Reports. The latter observer employed for inhalation the cultures of bacilli obtained from phthisical cavities. All the rabbits and guinea-pigs experimented upon either died or were killed within 28 days, and invariably the lungs contained numerous tubercles, which were also present in the liver and spleen of those who survived longest. In the rats and mice the same results obtained, but the tubercles were smaller and less numerous.

It must be said of Koch's results that the masses described present many of the characters of caseous broncho-pneumonia, or desquamative pneumonia, and when we remember how entirely Koch's diagnosis of tubercle is based upon the presence of the bacillus, rather than upon any other anatomical criterion, while in Wargunin's observations, made for the most part before those of Koch, the diagnosis was based upon anatomical characters which, until Koch's discoveries, were considered distinctive, we cannot but think that herein may lie the reason of the difference noted. Would Koch and his followers regard the nodules of broncho-pneumonia in Wargunin's dogs as tubercles? Here is an important point to be settled before the true value of Wargunin's, and even of Koch's, experiments can be estimated. Observers must agree upon an anatomical definition of tubercle.

LAPAROTOMY IMMEDIATELY AFTER RUPTURE OF THE CYST IN THE EARLY MONTHS OF EXTRA-UTERINE PREGNACY.

When rupture of the gestation cyst occurs in a case of extra-uterine pregnancy in the early months, the rule which has been urged by most obstetric authorities has been non-interference. But in 1849 an American physician, Dr. Harbert, suggested the propriety of laparotomy; and in 1866 the late Dr. Stephen Rogers, of New York, strongly advocated this practice in a paper read before the Obstetric Section of the American Medical Association. The late Dr. Parry, in his invaluable monograph upon Extra-uterine Pregnancy, published in 1876, gave this treatment his approval, but also stated that it had never been tried.

The trial has now been made, and with remarkable success. *The British Medical Journal*, for June 28th, contains a report of five cases of extra-uterine pregnancy, operated upon at the time of rupture, by Lawson Tait, and four of the patients recovered. Such a result is certainly very encouraging, especially when contrasted with that of the usually followed practice of non-interference; for, as observed by Dr. Parry, recovery is so rare that the physician has no right to allow the fact that it may occur to influence him in deciding upon a plan of treatment.

The difficulty of diagnosis has been presented by all who have considered the subject, as the chief objection to performing laparotomy; but Mr. Tait simplifies the matter by stating the question thus: If, however, it be found that the patient has been eight weeks or more without a period, that there is a pelvic mass on one side of the uterus and fixing it, and that sudden and severe symptoms of pelvic trouble and hemorrhage came on, the rupture of a tubal pregnancy may be at once suspected, and if an operation is to be done—and it clearly ought to be done—it must be done without delay.

The method of operation pursued by Mr. Tait is as follows: After opening the abdomen, the tube is tied below the point of rupture and cut off, and then the cyst, fœtus, and appendages, blood-clots and serum, are removed; in three of the cases the fœtus could not be found, but as two of these patients recovered, its being left in the abdominal cavity is shown to be harmless. An adherent cyst or placenta is not to be removed, but drainage of the abdominal cavity is then to be made.

We are glad to know that this plan of treatment, first proposed and urged by American surgeons, and put in practice by the bold Scotch surgeon of Birmingham, has proved so successful, and we feel hopeful that its general adoption will save many lives.

It is somewhat notable that Mr. Tait's statistics of laparotomy are directly the reverse of those given by Dr. Gaillard Thomas, in volume vii. of the Transactions of the American Gynecological Society. Of the results of non-interference in this accident, Dr. Thomas has seen five cases, of which four died, and one recovered.

At a meeting of the London Obstetrical Society, a little more than a year ago, Mr. Tait reported operating on seven cases of extra-uterine pregnancy, six of the patients recovering; two of these operations were done immediately after the rupture.

THE ABRUS POISON.

The seeds of the jequirity plant have been very extensively used in India for criminal poisoning, especially of cattle, and have been employed to some extent as a remedial agent. Further, MM. Cornil and Berlioz announced last year to the French Academy that their poisonous powers were due to the presence in them of a peculiar microbe. This, if true, is a most extraordinary fact, indicating that everything is to be resolved finally into germs, and making it probable that hereafter man will be found to be nothing but a compound animal, a sort of branching coral with the bones secreted by the innumerable polyps or microbes of which the human compound organism is formed.

These circumstances lend both practical and scientific interest to the elaborate investigation just completed by Surgeons C. T. H. Warden and L. A. Waddell of the Medical College Hospital, Calcutta. We are glad to announce and believe that there are other things in the universe besides bacteria, and that the *Abrus precatorius*, although not a virtuous plant, is not a germ factory, and does not spend its days and nights in the manufacture of bacteria, but accomplishes its nefarious purposes through a poisonous proteid—*abrin*—which seems to have many properties in common with the venoms of serpents. Messrs. Warden and Waddell seem to have done their work very carefully and thoroughly, and in their little brochure entitled "The Non-bacillar Nature of Abrus Poisoning," Calcutta, 1884, not only give a clear account of their methods and results, but also of the means of distinguishing the abrus roots from those of true liquorice, which they resemble.

LITHOLAPAXY IN MALE CHILDREN.

Up to the age of fourteen, unless the stone is very small, the rule has been to resort to lateral lithotomy in male children; but a new departure has been made by Surgeon-major Keegan, of Indore, who tabulates in the *Indian Medical Gazette* for May, 1884, 24 cases of rapid lithotrity in children, with a degree of success that must be considered phenomenal. 7 cases, however, would be more correctly described as "very thorough lithotrity," as a tube was not used to evacuate the fragments, while the seventeenth case, which proved fatal, must also be excluded, as not less than three operations were required, and the evacuator was used only at the second sitting.

Of the 16 cases of litholapaxy in the strict acceptation of that term, that is to say, of crushing and evacuation of the fragments at a single sitting, every one recovered. 1 child was twenty months of age, 1 two years, 1 three years, 1 four years, 5 were five years of age, 2 seven years, 3 eight years, 1 was ten years, and 1 twelve years. The smallest stone weighed seven grains and the largest two hundred and forty grains, the average weight being seventy-one grains. Of the 13 in which the composition of the calculus is noted, 10 were uric and 3 phosphatic.

The lithotrites employed corresponded to Nos. 5, 7, and 8 of the English scale and the evacuating tube was equal to No. 9 of the same gauge. The time required to complete the operation varied from four to seventy minutes, or thirty-eight minutes on an average, but Dr. Keegan states that he would not hesitate to keep the patient under chloroform for two hours if it were necessary.

The results which we have briefly outlined indicate that Dr. Keegan has opened up a new and wide field for litholapaxy, which we hope will be submitted to a fair and patient trial. The operation differs from that performed in adults only in the small size of the instruments used, which should be manipulated with a light hand and great gentleness.

Dr. William Osler, of McGill University, Montreal, is prominently and favorably mentioned in connection with the Professorship of Clinical Medicine in the University of Pennsylvania, rendered vacant by the transfer of Dr. Pepper to the Chair of Theory and Practice of Medicine. Dr. Osler is widely known as a talented scholar, a learned clinician, and a popular teacher, and his election, which

it is understood will be very acceptable to the Medical Faculty, would add undoubtedly to the high reputation which the University has always enjoyed.

Dr. Osler has just been invited to deliver, next spring, the Gulstonian lectures before the Royal College of Physicians of London, of which body he was elected a Fellow in May, 1883.

The proposed public exhibition in the eastern and western cities of lepers from California, if ever seriously contemplated, has received a check by the prohibition of the spectacle, which has been promised by the various boards of health. Whatever may be the object of the exhibitor, it is clearly certain that the subjects of the loathsome disease, together with their associates, will not be allowed the freedom of the cities, much less to display themselves in public. Should the attempt to come east be persisted in, it is more than likely that this coterie of lepers will find its movements circumscribed within the narrow limits of the quarantine station or the pest-house, until a final disposition shall be made of the case. Exclusion and isolation has long been the practice with respect to this direful malady, and it is not to be expected that it will be departed from at this day. Although the modern idea is opposed to the contagiousness of leprosy or its propagation by contact, the local authorities are justified in prohibiting so repulsive a spectacle as the exhibition of this disease would present.

SPECIAL ARTICLE.

NEW TESTS FOR ACETONE—ACETONÆMIA.

The complex of symptoms known as diabetic coma was first described by v. Dusch in 1857, shortly afterwards by Petters, Kaulich, and Cantoni—1857 to 1864—and has been more recently studied by Kussmaul, in 1874, and Frerichs, in 1883.

The symptoms are not invariably the same, but the presence of the condition is generally inferred if sleepiness and stupor, accompanied by frequent pulse, supervene upon the other symptoms of a diabetes mellitus. These phenomena are commonly gradual in their development, but there is sometimes met a more acute form, characterized by suddenness in the appearance of the above symptoms, to which are added gastric and intestinal disturbances—epigastric pain, vomiting, sometimes of blood, purging—a peculiar noisy delirium, panting respirations, and fluctuations in the rate of pulse, which continue until coma is thoroughly established, after which the pulse remains frequent and small. A peculiar fruity odor, like that of acetone, is sometimes exhaled by the breath and the urine. These symptoms occasionally disappear, but more frequently they terminate in death.

Even the earliest observers, Petters and Kaulich, regarded the condition as an intoxication due to a substance derived from some metamorphosis of sugar, resulting in the formation of alcohol and other products of alcoholic fermentation. Having been able, with more or less certainty, to demonstrate acetone in the blood and urine, they selected this substance as the toxic agent. But even they admitted that acetone might be present in the expired air and urine in other affections, as the acute exanthemata, pneumonia, diseases of the stomach, and in diabetes without coma. Still more recently, v. Jaksch, among others, has regarded acetone as a product of normal tissue-change as well as of disease.

It will be remembered that the test heretofore in common use for acetone is *chloride of iron*, recommended by Gerhardt. This observer discovered that there was occasionally a substance in the urine of diabetics and habitual drunkards which struck a red reaction with this reagent. He inferred that this was the source of acetone, and was probably ethyl diacetate. At the same time, this substance has never been isolated, and it is considered by some to be diacetic or aceto-acetic acid. It was also soon discovered that the chloride of iron reacts with other substances more liable to be found in urine than the acetone-producing agent, so that it can no longer be considered a safe test.

Another test is Lieben's *iodoform test*. Dr. Ralfe suggests the following method of using it: About a drachm of liquor potassæ containing twenty grains of iodide of potassium is placed in a test-tube and boiled; a drachm of the suspected urine is then carefully floated on the surface. When the urine comes in contact with the hot alkaline solution, a ring of phosphates is formed, and after a few minutes, if acetone or its allies are present, the ring will become yellow and studded with yellow points of iodoform. These, in time, will sink through the ring of phosphates and be deposited at the bottom of the tube. Von Jaksch, in his extensive experiments published in *Zeitschr. für klin. Med.*, Bd. v. Heft 3, 1883, applied the test to the distillate from urines. Lieben himself furnishes a list of nineteen substances, of which two are found with certainty in urine, viz., ethyl-alcohol and lactic acid, while the others, alcohol, aldehyde, and certain fatty acids, may be present accidentally or otherwise in normal and pathological urines.

More recently Penzoldt has made use of the *indigo reaction* suggested by Baeyer and Drewsen, and has published the results of an extensive series of experiments, as well as a *résumé* of the results of others, in the *Deutsches Archiv für klin. Med.*, Bd. xxxiv. Heft 2, Oct. 1883. The test is applied as follows: Heat a few crystals of nitrobenzaldehyde until dissolved, allow the solution to cool, when the aldehyde separates as a white cloud; then add the suspected fluid, and make it distinctly alkaline with dilute caustic soda. If acetone is present, there appears first a yellow, then a green color, followed by an indigo blue, in the course of ten minutes. If only traces of acetone are present, the yellow fluid is shaken with a few drops of chloroform, when a distinct blue coloration of the chloroform takes place.

By this method acetone can be easily detected in a dilution of 1 part to 2500, but for such delicacy the distillate must be used—about one cubic centimetre. The reaction is less distinct if the test is directly applied to urine, because of the coloring matters and other constituents, but acetone may be detected by the aid of chloroform, when in the proportion of 1 part to 1000. So far as known, pyroracemic acid, aldehyde, and aceto-phenon are the only substances producing the indigo reaction, and these have not as yet been found in urine.

Still another test is Legal's with *nitroprussiide of sodium and caustic potash*. These reagents strike a red color which passes over into purple on the addition of acetic acid. Kreatinin strikes a similar red color, which disappears when acetic acid is added. This test may also be applied directly to urine.

Penzoldt investigated 62 pathological urines, using for test purposes the first 2 cubic centimetres of the distillate from 300 of the acidulated urine. Of the 62 cases, 22 were diabetic. Of these, the indigo reaction was present but twice without chloroform, twice with chloroform, and in 18 cases was totally absent. Of the latter, the iodoform test responded decidedly in 7, in 6 moderately, and in 7 feebly. Two were not tried by the iodoform test. It will be seen, therefore, that this reaction was marked in several instances in which the indigo reaction did not respond.

Of the fever cases, 11 were typhoid, and in only 1 of these was the reaction decided without chloroform; in 2 with the aid of chloroform, while in 8 it failed altogether.

Out of 7 cases of pneumonia, the indigo reaction was decided in 6, and absent in 1 only.

It failed altogether in all of 6 cases of phthisis.

The reaction was present in 1 out of 3 cases of measles, and in the urine from 1 case of cerebro-spinal meningitis. Of the non-febrile cases, the reaction was found in 1 of old traumatic stenosis of the œsophagus in a child. In this case there was also a transient glycosuria, and the urine responded to the chloride of iron test as well; but both this and the indigo reaction disappeared the next day.

Thus, in the total of 62 cases, the indigo test for acetone was found but 12 times distinctly, and 6 feebly; while the iodoform test responded in almost every case, failing entirely in but 2 of the 52 in which it was tried.

It is evident from the above that the tests for acetone, or the acetone-producing substances, are far from being satisfactory. For it is impossible, in the present state of our knowledge, to say positively whether the indigo or the iodoform test is the most reliable. If we accept the indigo as correct, the number of cases even of diabetes in which acetone urea is present is very few; while if we accept the iodoform test they are quite numerous. But, when we remember that Lieben himself, the discoverer of the iodoform test, gives a list of nineteen other substances which respond to his test, of which at least five may occur in urine, while only three substances besides acetone, and of which none have as yet been found in urine, respond to the indigo test, it seems that the latter must be regarded as the more reliable.

It has already been mentioned that Petters and Kaulich supposed that acetone originated in certain fermentative processes of grape sugar, taking place in the gastro-intestinal canal, and especially the stomach, although without ever having proved it. According to Kaulich, Anthon obtained in the fermentation of grape sugar a fluid which was recognized as acetone by Prof. Lerch. Penzoldt mixed solutions of sugar with yeast and various fluids, such as decomposing urine, fermented stomach contents, intestinal fluids, decomposing cheese, rotten egg, and fever urine the distillate of which gave the indigo reaction, and allowed them to remain eight days, sometimes at the ordinary temperature, and sometimes at 100° F. The distillate of these mixtures had always more or less vinous odor, and responded distinctly to the iodoform reaction, but not to the indigo; but it cannot be claimed for these experiments that they settle the question as to which is the better test.

As soon as acetone, or the acetone-producing substance, was detected in the urine it was suspected that the symptoms in diabetic coma were caused by it, and Kussmaul early sought to settle the question by experiment. In man, doses of 6 grammes a day produced no effect. In rabbits 6 cubic centimetres, administered subcutaneously in divided doses, produced symptoms of intoxication with stupor. The same results followed inhalation in the case of rabbits, but failed in the case of dogs. Whence Kussmaul concluded that the diabetic coma was the result of an acetonæmia. Against this view there has been some reaction, Frerichs and his pupils having obtained different results in their experience, whence they concluded that there was no such thing as acetonæmia.

In the article referred to, Penzoldt has attempted to reconcile the apparent incompatibility of the view that the symptoms of diabetic coma are due to acetonæmia, with the ineffectual results of experiments and the exceedingly small amount of acetone found in the secretions. He first calls attention to the fact that the very small amount of lead found in the tissues and secretions in lead-poisoning is not considered incompatible with the view that the symptoms are caused by lead, although much larger doses are needed to produce the symptoms of lead-poisoning than the quantities thus obtained. Secondly, it makes some difference whether the poison is introduced into the system interruptedly from without, as is done in experiments, or whether it is continuously produced in the organism. Thirdly, the substance in the nascent state may act more deleteriously than that which has been some time formed. Fourthly, poison continuously absorbed sometimes produces a chronic poisoning which may quite suddenly assume an acute character, as delirium tremens in chronic alcoholism. Finally, we can only judge of the action of a substance when we compare its excretion with its formation, as a poison which is excreted as fast as it is produced cannot be expected to exhibit potent effects. Acetone is rapidly excreted by the lungs, and no experiment with it is complete unless this excretion be kept in view. Accordingly, Penzoldt took three rabbits of equal weight from the

same litter. To one (A) was administered, subcutaneously, one gramme of pure acetone, and the animal placed under a small bell-glass. A second (B) was similarly placed without acetone. A third (C) received also a gramme of acetone subcutaneously, and was set free. In ten minutes A was restless, dizzy, dyspnœic; B normal; C stupid, and did not retract its hind legs when they were drawn out. In fifteen minutes A lay on its side, B showed scarcely any dyspnœa, C was dizzy and remained a short time on its side when put there. In three-quarters of an hour A was stupid and dyspnœic, with eyes half closed; B began to breathe somewhat more deeply; C was still staggering, but walking. Still later the condition of A became more intensified, while C was again normal. After two and a half hours A lay at the point of death, B was strongly dyspnœic, but still strong and on its legs. The animals were then removed from the bells and revived.

These experiments were further so modified as to permit the acetone to be inhaled, with similar results. Whence Penzoldt inferred that acetone causes in rabbits continued somnolence and stupor if its excretion by the lungs is interfered with, and that while the doses required to produce these effects cannot be considered small, they cannot, on the other hand, be regarded as excessively large. Whence we have only to suppose the temporary or permanent interference with the excretion of acetone by the lungs in diabetes to be able to account in a perfectly satisfactory manner for the phenomena of diabetic coma. Such a condition may be found in the lung complications which so constantly attend diabetes. A parallel is seen in the interference by the altered state of the uriniferous tubules of the kidney with the elimination of urea, and the consequent uræmic symptoms. At the same time, Penzoldt well says that it would be as much a mistake to ascribe all the symptoms of diabetic coma to the retention of acetone as it would be to refer uræmia in Bright's disease to the retention of urea alone. As in the latter case there may be allied substances, so in diabetes there may be substances allied to acetone which unite with it in producing the peculiar symptoms of diabetic coma.

One more point in connection with this very interesting and not unimportant subject, and bearing also on Penzoldt's experiments. It will be noted that acetone was revealed by the indigo test in six out of seven cases of pneumonia. Now in pneumonia, in which the air-vesicles are completely filled over a large portion of the lung, we can understand that the elimination of acetone is largely interfered with, much more so than in cases of phthisis. Hence, supposing it to be a normal product of tissue-change, we should expect it to accumulate in the blood and to appear in the urine; while in cases of diabetes mellitus, in which we may resonably suppose it to be found in abnormal amount, we should expect it to be found in greater quantity in the urine in those cases accompanied by a lung complication. Attention should be directed to these points by clinicians.

REVIEWS.

Elements of Pharmacy, Materia Medica, and Therapeutics. By William Whitla, M.D. (G.U.I.), Physician to the Belfast Royal Hospital. With lithographs and woodcuts. Second edition. 12mo., pp. 602. London: Henry Renshaw, 1884.

This valuable little manual is intended to give to the student of medicine such information in a concise form as he generally has to sift out of two or three larger handbooks; and certainly the author has generously carried out his intention. The book contains all in its own branches that a busy practitioner could wish to be able to find at a moment's notice; pharmacy, materia medica, and therapeutics each receiving a proper amount of consideration. The last two hundred pages of the book are given to the discussion and description of non-officinal remedies, the administration of medicines (including a valuable chapter on prescription-writing), and pharmacopœial reactions and tests, with tables of weights and measures, an excellent index, and an index of poisons and their antidotes.

The volume is well worth a place upon the table of every practitioner of medicine, as a means of rapid reference.

The Physician's Combined Day-book and Ledger. By H. T. Hanks, M.D., New York. For sale by J. H. Vail & Co., 21 Astor Place.

To no business man is a ready and at the same time infallible system of bookkeeping more important than to the physician. Compelled for the most part to keep his own accounts, and to make out his own bills, his time is generally so much occupied that it is impossible and unprofitable for him to follow an elaborate system. At the same time, it is well known that physicians lose much money because of their constant failure to note visits and other services.

The day-book and ledger of Dr. Hanks seems calculated to meet all the requirements of our profession. The bookkeeping is compact, the account is easily followed, there is no transfer or extra posting, and the book is adapted for city or country practice, and to many or few patients. A little careful study of the method shows it to be simple and easily understood, and we believe physicians will find it useful.

SOCIETY PROCEEDINGS.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, May 5, 1884.

William Hunt, M.D., in the Chair.

Dr. Ferdinand H. Gross exhibited a

TUMOR OF THE MALE MAMMARY GLAND,

which he had removed from a male patient at the German Hospital. The man was fifty-eight years of age, a German, who, in his own country, had followed the occupation of a tailor, but in this country had become a confectioner. He presented a pale, cachectic appear-

ance, but was not markedly emaciated. From his own account, he descends from a stock remarkable for longevity. The patient knows of no cancerous disease or other tumors to have occurred in any of the members of his family. There appears, therefore, to be no hereditary taint associated with his disease. About two and a half years ago he noticed, for the first time, several small lumps or swellings beneath the skin on different parts of the right side of the chest. They were scattered over an area beyond the region of the mammary gland, would remain for a time, and then disappear. About four months ago he was taken ill, and confined to his bed for several weeks. His physician told him that his liver and kidneys were affected. The skin was jaundiced, and his urine was very high colored. As he was recovering from these troubles, between two and three months ago, he noticed a hardened, round tumor, about an inch in diameter, in the region of the right nipple. About a week later it began to ulcerate at a point resembling a small pimple. Previously he had not noticed an involvement of the skin. The ulcer has extended to the size of a dime. The growth was not continuously painful, but occasionally darting pains were experienced in this region, and these were at times quite severe. The lymphatic glands in the neighborhood, as in the axilla, are not enlarged or painful.

Dr. Gross believed the neoplasm to be scirrhous in character; but, as it had been removed only a few hours before the meeting, a minute examination had not been possible.

The case was specially interesting as occurring in the male, and a committee, consisting of Drs. F. H. Gross, J. M. Barton, and S. W. Gross, was appointed to make a microscopic examination, and report at a future meeting.

Dr. Nancrede asked if any of the Fellows had had any experience with the comparatively new method called deep canalization, whereby immediate union is obtained without the use of drainage-tubes, and not more than one dressing. There are two methods of performing this. He had tried one, and it was very satisfactory, except that the relaxation-suture gave way, with consequent strangulation of the middle part of the wound.

The method of performing this operation is to make a number of oval holes in the skin (about four), two-thirds of a centimetre in their long diameter, at the lower portion of the posterior axillary fold, then introduce a relaxation-suture to take off the strain. The edges were coaptated by a continuous catgut suture. In his case, this suture, which was of catgut, gave way. There was a normal temperature in this case until the eighth day, when a little sloughing occurred. He believes that if he had used a metal suture only one dressing would have been required. The wound was dressed with the corrosive chloride solution. Gerster reports three cases, one of which was well on the fourteenth day, another about the thirteenth or fourteenth, and a third on the twenty-first day. These cases required only one dressing beside the primary dressing. Where the skin cannot be brought together, it has been suggested to stitch the skin to the anterior and posterior axillary folds, so as to leave an open surface for drainage.

Dr. Barton said that the method suggested by Dr. Allis is valuable in cases like this. He takes a broad strip of plaster and runs it to the very edge of the incision, and the same on the opposite side. He then carries the stitches through both the skin and the plaster. This plan is valuable where considerable strain has to be put on the sutures.

Dr. Packard said that it might seem superfluous to mention any other method, but the one to which he desired to call attention is entirely analogous to the old dry suture, There is a form of plaster now made which enables us to use the dry suture to greater advantage than formerly. This is the porous plaster. It is not irritating to sound skin. He had used it to great advantage by applying a piece of plaster to each side of the wound, and instead of passing the sutures through the skin and the plaster, he simply laces them through the holes of the plaster, This is sufficient to bring the edges of the skin together, and prevents the irritation of the deeper parts which follows the introduction of sutures. If desired, the lacing can be readily undone and the wound dressed. The dressing may be placed below the sutures, if it is wished, or it may be placed above. This plan has been very efficient in his hands.

There is another point to which it is, perhaps, well to refer, and that is in regard to the removal of plasters, and especially of large ones. It is not necessary to remove the whole strip, but simply the portion on each side of the wound should be cut away and the plaster spliced with a new piece.

In regard to applying the porous plaster to irregular parts, the plaster may be cut in strips and the ends of these strips united according to the nature of the part. There are many cases in which it is desirable to avoid sutures, and in such cases this plan may often be adopted.

The skin, he thinks, stretches to a greater extent than is usually supposed. He mentioned a case at the meeting of the American Surgical Association, at Washington, that of a man who was caught in machinery and had a comminuted fracture of the forearm, and a compound comminuted fracture of the arm for about three-fourths of its length. The skin was torn to such an extent that there was no possibility of covering the stump. The skin was stripped entirely from the arm, leaving the muscles bare. This man was brought into the hospital in the evening. He saw him the following day; he was still in good condition. He decided that the proper thing to do was to relieve him of the arm. He made an ordinary double-flap shoulder-joint amputation, through the muscles alone. He brought the skin together as near as possible from the front and back with two long shawl-pins, and over these he made a figure-of-8, with a piece of narrow bandage, as he feared the tension of a ligature. The wound was dressed with carbolized oil, in the ordinary way, The man made an uninterrupted recovery. At one time he was greatly prostrated with diarrhœa, and lost flesh, but he recovered from this. He saw him two weeks ago, and the only point that is liable to give trouble is where the cicatrix passes over the point of the acromion and clavicle. Here there seems to be some tension, but it does not give the patient any inconvenience.

Dr. Pancoast, as a dressing for harelip, uses a strip of adhesive plaster long enough to go around the skull and to roll up at the ends into little pads. By this means the projection of the nose is surmounted. This

forms a useful way of supporting the cheeks. He also uses, in addition, to approximate the margins of the skin, fine black silk sutures.

DR. NANCREDE said that in removing the mammary gland he uses a free incision, and one that makes but little angle. He then introduces sutures, five inches from the edge of the wound, using the buttons introduced by Cheyne. With these buttons the greater part of a large incision can be coaptated, and union by what is called first intention may be secured. He has also used the button-suture as a relaxation-suture. The method of Dr. Packard is exceedingly ingenious, and he will try the long strips when he has an opportunity. The large pieces would, he thinks, interfere with the stretching of the skin.

DR. J. EWING MEARS said that the essential feature of the modern treatment of wounds is to secure, if possible, such thorough coaptation, approximation, and relaxation of the edges of a wound that primary union may take place. For this purpose three forms of suture are used: 1. The suture of coaptation, which is to bring the edges together. 2. The suture of approximation, which is passed a little further from the edges than the first suture. 3. The suture of relaxation, which is introduced at a still further distance from the edges of the wound. In order properly to apply this suture, the buttons referred to by Dr. Nancrede should be employed. With these three forms of suture there is no difficulty, in most cases, in bringing the parts together, and the edges can be approximated without the danger of causing tension, which develops irritation. That is an important feature of the modern method of wound treatment. He thought that any one who has studied the antiseptic method of treating wounds will find that, as a rule, plasters are dispensed with. Dependence is placed on these sutures. He thought, therefore, that if we adopted the modern antiseptic methods of treating wounds, we should give up plasters largely. As to Dr. Packard's suggestion in regard to the removal simply of that portion of plaster which covers the wound, this plan was described by the late Mr. Callender at one of the New York college clinics, during his visit to this country.

DR. PACKARD said that he certainly did not intend to claim any originality. He did not know whether it was described by Mr. Callender or not. It seemed a suggestion which would naturally occur to any one who pays attention to diminishing the suffering of the patient.

It seemed to him that we could scarcely dispense with plasters. He conceded that great improvements have been made in the sutures. One thing that we do now is to use deep sutures and use relaxation-sutures. He thought the button-suture a great improvement. He was a little surprised to hear that the great point in the modern treatment of wounds is to secure approximation. He should say that the other tendency is the one which is now predominant: that large incisions may be made and the wound be allowed to heal by granulation. Tumors are now removed, which, twenty years ago, the best surgeons would have left alone, because they had not learned that wounds will granulate from the bottom.

Four years ago he removed a tumor from a patient; she made a good recovery, but this winter there was a return of the disease beneath the cicatrix. There was a large mass near the middle line, the removal of which produced a wound which it was impossible to close. It was dressed with carbolized oil. After a time it was sprinkled with borax and then astringent applications were used. The wound is now no larger than a ten-cent piece. We are coming to the idea that we can allow wounds to close up by granulation under antiseptic and astringent dressings.

CORRESPONDENCE.

CIDER VINEGAR IN THE TREATMENT OF DIARRHŒA AND DYSENTERIC SYMPTOMS.

To the Editor of THE MEDICAL NEWS.

SIR: The apprehension of the danger threatened by the Asiatic cholera, being already accompanied by an amount of diarrhœa and dysentery in most communities, it seems incumbent again to call attention to the internal administration of cider-vinegar as being followed by such remarkably happy effects upon such maladies.[1]

It has recently been said that the cholera microbes are destroyed by acids, and that alkalies favor their generation. Pure lemon-juice is reported to have been recommended abroad for diarrhœa, and the general opinion that the fermented acids from fruit juices, are dangerous in such diseases, seems about to be proved erroneous, or at least found liable to very pronounced exceptions.

In these affections when the contraction of the sphincter ani muscles demands an effort on the part of the will, merely bringing vinegar in contact with the tongue inaugurates a reflex action upon the nervous system and probably the lower portion of the spinal cord, that almost invariably relieves the patient. The cramps, tenesmus, and chills that are so distressing, are quickly combated by a draught of the remedy and succeeded by a glow of the most natural and comforting character.

Vinegar swallowed in doses of a teaspoonful by young children, and a wineglassful by adults, may be repeated several times if the pain returns or the evacuations of the bowels recur, until generally after the third, but most frequently after the first administration, there seems to result a complete cure and this too without any necessity in ordinary cases for positive restrictions of motion or diet.

This has been so safe, rapid and complete a cure in both recent and chronic cases, that to enumerate them here, would seem less likely to convince doubters of its efficacy, than to cause them to suspect it as savoring of the sentiments of reports of the advertised nostrums.

A food of the class of condiments, so universally used, being mentioned by the early biblical writers and known as a part of the diet of millions of soldiers from the time of the Romans to the present, would seem to encourage the conscientious study of articles of daily and familiar use, for the discovery of new capabilities. Doubtless there are many simple and efficient remedies at our command, that have been overlooked through their simplicity and innocuousness.

The aphorism of Sydenham, that "the nearer a medicine approaches a food the more efficient it

[1] See American edition of Coleman's Dental Surgery and Pathology, p. 32.

becomes"—excites the hope that it is pardonable to attempt the persuasion of others to test this plain acquaintance and thus see if it is not worthy of greater respect in the pharmacopœia.

Earnestly desiring that the mention of the experience of the writer may aid in causing others to essay it and that thus the benefits of this remedy may be fully reaped by all through its most wide publication in your journal,

I am very sincerely yours,

THOMAS C. STELLWAGEN, M.D.

PHILADELPHIA, 1627 CHESTNUT ST.,
August 1, 1884.

P. S.—Since the above was in print, I have received, through the kindness of Prof. Alfred Stillé, M.D., an extract from the *Journ. de Méd. et de Chirurg. prat.*, viii. 432, which speaks of the employment of very sour (très vinaigrée) lemonade, or pure vinegar, in sixteen cases of what are called epidemic cholera, with twelve recoveries.

This article further states, "All the symptoms of Asiatic cholera were found united in these patients with the exception of the cyanosis, which was wanting in the most of them." Can the prompt use of the vinegar have prevented this almost fatal although crucial symptom?

NEWS ITEMS.

CHOLERA PRECAUTIONS IN THE UNITED STATES.—The Massachusetts and Connecticut State Boards of Health last week issued circulars to the public containing suggestions relative to epidemic cholera, and urging the importance of public and private sanitation and disinfection.

The Government is establishing a quarantine station at or near the "Delaware Breakwater" for the purpose of preventing the introduction of infectious diseases by foreign vessels which anchor at the Breakwater before proceeding up the Delaware River. This action is taken at the request of the Wilmington Board of Health.

THE PARIS ACADEMY OF MEDICINE ON CHOLERA QUARANTINE.—At its meeting on July 15, the Académie de Médecine of Paris formally adopted the following propositions:

1. Land quarantine, whatever be the form under which it is established, is impracticable in France.

2. The disinfection procedures carried out on travellers and their baggage in the railway stations are inefficacious and illusory.

3. Medical posts should be established in the large railway stations, in order to give assistance to the sick, and to isolate them from the other travellers.

4. The efficacious measures of protection are those which every person should take for himself and his house. It is the duty of municipalities to see that the rules relating to the isolation of the sick, the disinfection of linen, clothing, rooms, etc., are rigorously carried out; and that the precautions of private and general hygiene are strictly followed.—*Gaz. Méd. de Paris*, July 26, 1884.

PREPARING FOR CHOLERA IN PARIS.—A correspondent of *The Lancet* writes from Paris, under date of July 22d, that the cholera more than ever engrosses public thought, and in medical circles is the principal, if not the only, subject of discussion. Nor is this solely a matter of conversation. Two notable measures have been adopted. Dr. Dujardin-Beaumetz, Member of the Council of Hygiene and Salubrity for the Department of the Seine, is organizing throughout Paris a sanitary service. Medical officers of health are now being appointed for every district. Orders are given that any illness of a choleraic nature must be reported at once to the nearest police station. The prefect of police is then communicated with by telegraph, and the medical officer is ordered to superintend personally the disinfection of the house where the case is reported. But the question arises as to what is meant by the term disinfection, and who is to do the work which these newly created medical officers are called upon to superintend. So far either policemen or firemen have been employed; and, on the whole, a distinct preference is shown for the latter. They are brave, active, and accustomed to constant alarms; on the other hand, they are young men, very susceptible to contract diseases, and may possibly infect the barracks in which they live. The term disinfection is also employed in a very vague manner. It generally means a good scouring, and but for the plentiful use of carbolic acid or chloride of lime would be little better than an English "spring cleaning."

While, however, Dr. Dujardin-Beaumetz is organizing the machinery for the disinfection of houses, M. Pasteur is conducting a series of experiments for the purpose of ascertaining what may be considered effective disinfection. In conjunction with several other medical men, some civil engineers, and the prefect of police, M. Pasteur has been every morning to the Hôpital Cochin, where experiments were organized in the following manner. M. Pasteur selected from his laboratory the microbes of chicken cholera, of anthrax, lymph of smallpox (both moist and dry), and other similar subjects. These specimens were divided into three equal parts, and placed in three different small rooms at the hospital. In one room common sulphur was burnt; in the second liquid sulphurous acid was injected through the door by M. Pictel; and nothing whatever was done to the third room. After twenty-four hours the microbes were examined, and calves were vaccinated with the smallpox lymph. The result so far goes to show that the sulphurous acid, whether derived from the fumes of burning sulphur or from M. Pictel's siphon bottles containing the liquid form, did not disinfect at all.

M. Pasteur showed me some cultures, notably those of splenic fever, which had developed themselves with great activity in spite of twenty-four hours' sojourn in the midst of sulphurous acid gas. At the same time, I must state that the experiments were in no wise conclusive. The amount of sulphur employed was small —750 grammes to 80 cubic metres,—and now the experiments are being repeated with a far stronger proportion of sulphurous acid; and if the liquid form is employed, there will be no difficulty in attaining the required strength. But this is expensive. At present five francs a litre is the price demanded, though probably this will be reduced to two or three francs. Yet even at this price the disinfection of a room will cost from ten to twenty shillings, according to its size.

The Hôpital Bichat and the Hôpital Broussais will be devoted especially to the treatment of cholera cases should the epidemic break out in Paris.

CHOLERA PRECAUTIONS IN GERMANY.—The following regulations have been promulgated by the Berlin Board of Health:

Especial attention should be paid to the general health of the people, in order to prevent a disposition to cholera from disorders of the digestive organs. Care should be taken that persons thus affected should have the necessary medical attention as soon as possible.

In places affected by cholera, the following rules are to be observed: The first cholera patients are to be isolated in their homes, or else carried to a cholera hospital. The latter should be done when the surroundings of the patient are unfavorable for treatment at home. Public carriages should not be used to transport cholera patients. If one has been so used, it must be disinfected before being again used for any purpose. The bodies of persons dead of cholera must be removed from the house as soon as possible; and a special place for their reception should be provided for these corpses. Towns which have no special place for their burial, should provide one.

Rules for Disinfection.—1. The discharges from cholera patients must be placed, as soon as possible, in vessels containing 1 part of pure carbolic acid to 18 parts of water. The quantity of the disinfecting material should be at least one-fifth of the material to be disinfected.

2. Body- and bed-linen soiled with cholera discharges should be immediately placed in this solution, and left therein for forty-eight hours, and then washed in water.

3. Clothing, beds, and other articles which cannot be treated in this manner, should be disinfected by steam.

4. Furniture and floors soiled by the discharges should be cleansed with dry rags, which must then be burned or placed in the carbolic solution.

5. All persons who come in contact with cholera patients or their effects, or are soiled by their discharges, should thoroughly disinfect and wash their hands with the carbolic solution before going into the presence of other persons or eating anything.

6. In carrying out disinfection by means of steam, only such apparatus is necessary as will carry a spray of steam through the room to be disinfected and raise the temperature in the room to at least 212° Fahr. This can be regulated by a thermometer. The time necessary for disinfecting different things may be put as: For clothing, not less than one hour; and for articles difficult to penetrate, not less than two hours. Of course, the time is not reckoned until the temperature reaches 212°. The steam is better developed in a steam-kettle, and carried into the room to be disinfected through a pipe. Instead of a steam-kettle, a very large boiler may be used; and the articles may be placed in it and boiled.

Where such measures cannot be employed, as with bolsters, feather-beds, mattresses. etc., a continuous airing for six days in a warm, dry place, protected from the rain, may be employed. Sleeping-rooms in which cholera patients have lain, are to be cleaned, and aired for six days, and then thoroughly dried with heat.

7. Articles of little value should be burned when soiled, rather than disinfected.—*Berlin. klin. Wochensch.*, July 21, 1884.

CHOLERA PRECAUTIONS ON THE ITALIAN FRONTIER.—Six thousand persons are reported to be detained in the various lazarettos on the Italian frontier and along the coast.

PRECAUTIONS ELSEWHERE.—The ports of Brazil have been closed to vessels from Marseilles, Toulon, Spezzia, and all ports at which cholera prevails. The authorities at Madeira have refused to allow passengers and mail on a steamer which has arrived there from England to land.

AN ENGLISH CHOLERA COMMISSION.—The English Government has directed DR. KLEIN and DR. HENEAGE GIBBES to proceed forthwith to India to pursue a scientific inquiry into the nature of cholera. It is understood that these gentlemen will act in conjunction with the Commission nominated a few weeks ago by the Indian Government for the same object.—*Lancet*, July 26, 1884.

YELLOW FEVER PRECAUTIONS.—Inspectors have been appointed to accompany railroad trains leaving Guaymas, Mexico, for the United States, and prevent the passage of persons suffering with yellow fever from entering at El Paso, or Nogales. Sanitary Inspector Ross reports several cases having been put off at Hermosillo, and that there are six cases in the railroad section-house there, employés of the railroad.

The United States Consul at Mazatlan, Mexico, reports the existence of yellow fever at that place, and states that clean bills of health however are furnished vessels by the Board of Health of Mazatlan.

THE NATIONAL BOARD OF HEALTH.—The National Board of Health held its annual meeting on July 30th, and elected officers for the ensuing year as follows: President, Dr. James L. Cabell, of Virginia; Vice-President, Dr. Stephen Smith, of New York; Secretary, George E. Waring, Jr., of Rhode Island; additional members of the Executive Committee: Thomas Simons, Department of Justice; Dr. Charles Smart, U. S. A., and Dr. T. S. Verdi, of Washington. The following resolution was adopted:

Resolved, That in view of the possible invasion of the country by cholera, and of the existence of epidemics of other diseases, and in view of the duty imposed upon the Board by law "to obtain information on all matters affecting the public health," the Executive Committee is directed to put on duty such members of the Board as in its judgment may be necessary.

At a meeting of the Executive Committee the following was passed:

Resolved, That the members of the Board be placed on duty for the investigation of all matters which, in their judgment, have direct bearing on the question of cholera as a present menace to the public health, and epidemic of other diseases existing in the country. Congress having failed to make appropriation for the purpose, it is understood that such duty is to be performed without compensation.

THE COPENHAGEN CONGRESS.—The *British Medical Journal* announces that it is officially informed that the International Medical Congress at Copenhagen will be held as originally announced, and will not be postponed on account of the appearance of cholera, as has been suggested.

ORIGINAL LECTURES.

A COURSE OF LECTURES ON DERMATOLOGY.

Delivered at the University of Pennsylvania during the Session of 1883–1884.

BY LOUIS A. DUHRING, M.D.,
PROFESSOR OF DERMATOLOGY IN THE UNIVERSITY.
(Reported by Henry Wile, M.D.)

LECTURE VI.

ATROPHIES; ALBINISM; VITILIGO; CANITIES; ATROPHIA CUTIS; STRIÆ ET MACULÆ ATROPHICÆ; ALOPECIA; ALOPECIA AREATA; NEOPLASMATA; KELOID; MOLLUSCUM FIBROSUM; XANTHOMA; RHINOSCLEROMA; LUPUS ERYTHEMATOSUS; LUPUS VULGARIS; SCROFULODERMA.

ATROPHIES are characterized by diminution or degeneration of the elements of the skin. The process may be a simple atrophy, as of pigment in canities, or an atrophy and a hypertrophy combined, as in vitiligo, or, still further, a degenerative atrophy of the skin and subcutaneous connective tissue, as in morphœa. The pigment, skin proper, subcutaneous connective tissue, hair and nail, may all suffer from atrophy.

ALBINISM is a congenital absence of pigment, either partial or universal, of the skin, hair, iris and choroid coat The hair is usually white or yellowish and silky. The persons thus affected are called *Albinos*. The condition occurs among all races, of the north as well as of the south, and constitutes a curious anomaly. Partial albinism sometimes occurs especially in negroes, who are spoken of as "pied" or "piebald." Interesting cases of albinism were those known as the Cape May Albinos, where the parents were negroes having six children, three of whom were Albinos and three were black.

VITILIGO is an acquired disease, coming on at any age after birth, and is characterized by defined, rounded, ovoid or irregularly shaped patches of whitened skin surrounded by a variable amount of yellowish or brownish pigmentation. It usually begins in one or several places, which are pinkish or whitish, and surrounded by a brownish areola. These spots vary in size from a coin to the palm of the hand, and have a tendency to coalesce, forming larger patches. It is an atrophy of pigment surrounded by a hypertrophy of pigment, or a diminution of pigment surrounded by an excessive amount. The regions most commonly affected are the face, backs of the hands, and the trunk. When marked on the trunk it is not so apt to attack the hands or face. The course is, as a rule, slow, extending over years. The disfigurement is marked if occurring about the face or hands. There are no subjective symptoms, nor is there any disturbance of the general health. The disease is under the influence of the nervous system.

It is to be distinguished from chloasma in that the latter affection consists of yellowish or brownish spots without whiteness; also from tinea versicolor, in which there is more or less furfuraceous scaling, the scales containing a fungus. In the way of treatment, much can sometimes be done. Arsenic used judiciously, in small doses, for a period of months or years, is in some cases followed by marked improvement. Local treatment is of no avail. The prognosis should always be guarded, as the disease may last a lifetime.

CANITIES, or graying of the hair, may be either premature or due to old age. It may be partial, occurring in streaks or locks, or it may be universal. The color is variable, sometimes being one shade, sometimes two shades, as in Mr. Wilson's case, in which the hairs in their entire length presented alternate brown and white markings, the latter marking being supposed to be due to the presence of air globules. The hair may also change color, as a yellowish shade may turn into a black, or a brown into a red. Changes may also occur after severe illness, as after scarlet fever, brown hair being replaced by white. As a rule, time is required for alteration of color, but the question has often arisen as to whether a change could take place suddenly, and this question may be answered in the affirmative. Under nervous shock, or strong emotional influence, sudden graying of the hair may take place. Some authorities, as Wilson, explain the phenomenon by the presence of air bubbles in the hairs.

ATROPHIA CUTIS, or atrophy of the skin proper, is by no means common. In simple atrophy, where there is a diminution of the cutaneous tissue-elements, the skin presents a thin, dry, shrivelled appearance, and in degenerative atrophy, where there is structural change without loss of substance, the skin is somewhat hardened, and presents a waxy, fatty appearance. It may occur in streaks, spots or patches, or it may follow other processes, as lupus erythematosus, syphilis, seborrhœa and tinea favosa. *Glossy skin* is a condition due to impaired nutrition occurring about the extremities, especially the fingers, consisting of pinkish, reddish, smooth, shining lesions, like chilblains. *General idiopathic atrophy* comprises such cases as have been described by Wilson, Hebra, Hutchinson, Taylor and others, and known under the name of "xeroderma of Hebra," or "parchment skin." The condition is allied to morphœa, and the lesions exhibit a tendency to develop into epithelioma. They are disseminated, and consist first of a congeries of bloodvessels, accompanied by pin-head to split-pea-sized telangiectases and excessive pigmentation.

STRIÆ ET MACULÆ ATROPHICÆ may be either idiopathic or symptomatic. The former manifest themselves as lines, one or two inches in length, or as pin-head to finger-nail-sized, round or oval spots, presenting a smooth, shining surface. These are seen most frequently about the pelvis and on the flexor surfaces. The latter consist of those atrophic lesions brought about by overdistention of the skin, as seen in pregnancy and ascites.

Alopecia is a term used to express more or less complete, partial or universal baldness, irrespective of cause. The varieties are as follows: In *congenital alopecia* it may be partial or entire, usually the former. In one case, reported by Schede, excised portions of the scalp failed to reveal under the microscope the presence of hair-bulbs. *Senile alopecia*, or baldness of old age, is characterized by the permanent loss of the hair, accompanied by atrophy of the skin. The affection begins about the crown of the head, the hairs, often first turning gray, become thin, dry, and finally fall out. Men are more frequently affected than women. *Idiopathic premature alopecia* begins, as a rule, between the ages of twenty-five and forty, and may run a slow or rapid course. The hairs fall out without apparent cause, and are at first replaced by finer hairs, which in turn are shed. It also usually begins about the vertex and extends forward. It is very common, and is found more frequently in males. *Symptomatic premature alopecia* is a form of baldness which may accompany or follow certain diseases, and may be temporary or permanent. Such a condition may occur after nervous shock, severe fevers, protracted seborrhœa, lupus erythematosus, certain parasitic diseases of the scalp, leprosy and syphilis. *Syphilitic alopecia* is generally one of the early manifestations of syphilis, and occurs before the syphilodermata, or later, as a result of ulceration. As one of the early symptoms, it gives the patient much concern, as it is sometimes copious, involving even the eyebrows and eyelashes. It lasts usually but a few months.

Alopecia areata is an atrophic disease of the hairy system, appearing usually in the form of whitish, smooth, bald patches, of varying size and shape. It may come on suddenly or gradually, generally first invading the parietal or occipital regions of the scalp; it may also affect other hairy parts of the body. The patches are usually rounded, vary in size from a coin to the palm of the hand, are smooth and polished, and are whitish in color. Occasionally there are a few short, atrophied hairs to be found, but as a rule the hair-follicles are shrunken, closed, the skin becoming thin, similar to that of an old man. The course of the disease, whether left to itself or under treatment, is variable, months or years elapsing before complete recovery sets in. The latter may never occur. The prognosis varies according to the history and duration of the disease and the age of the patient. The younger the individual, the more favorable. In young persons, complete restoration of the hair is the rule, the patches first being covered with lanugo, and later by the normal growth. In some cases recovery sets in spontaneously.

The causes are not well understood. It is not of parasitic origin. It is attributed to nerve disorder, producing a temporary arrest of nutrition. The disease may be regarded as a tropho-neurosis. Microscopic examination of the hairs reveals atrophy of the bulbs. It may be confounded with tinea tonsurans, and cases have been recorded in which the two diseases existed together. But the blanched, atrophied condition and smoothness of the patch, and the absence of fungus in the former, are sufficient to give the diagnosis.

As regards the treatment, locally, a number of remedies exert a good influence; for example, sulphur, some of the mercurial salts, tar, oil of cade, and carbolic acid. The following prescription may also be used, full strength or diluted, as a stimulating lotion:

℞.—Tr. cantharidis,
Tr. capsici, ... āā f℥jss.
Ol. ricini, ... f℥ij.
Spts. lavandulæ,
Spts. rosmarini, ... āā f℥ss.—M.
Sig. Apply daily.

Ointments of tar and of sulphur are, perhaps, our most valuable remedies. Blistering is recommended by some, also turpentine, and mercurials, as ammoniated mercury, forty to one hundred grains to the ounce. As regards internal treatment in alopecia areata, arsenic is the best remedy, and, given in tonic doses for months, will in some cases be followed by good results. In this disease, local measures, as a rule, exert no influence until after the hairs begin to grow.

Atrophy of the hair takes place as a result of certain diseases of the scalp, or certain constitutional diseases, as syphilis. The hairs become fragile and dry, and sometimes have a tendency to split in the follicle, producing irritation. It is due to improper nutrition. *Trichorexis nodosa* is another peculiar condition of the hair, in which there is a series of small, spindle-shaped, bulbous swellings along the shaft, looking not unlike nits. The free end of the hair is split up, and presents a brush-like appearance. *Piedra*, also a nodosed condition of the hair, occurring in Colombia, is said to be due to a fungus.

Atrophy of the nail is as a rule acquired, and is characterized by a dry, brittle, "worm-eaten" condition. It may be due to syphilis, eczema or psoriasis; also to the fungus of tinea favosa and of tinea tonsurans. For simple atrophy of the nail, and that due to eczema and psoriasis, arsenic is the best remedy.

Neoplasmata, new growths, comprise a large and important class of diseases. They are composed of connective tissue, as xanthoma and molluscum fibrosum, or of a cellular deposit, as in lupus and syphilis. New growths may be either benign, as xanthoma, or malignant, as cancer, or intermediate, as lupus. They are, as a rule, not painful, and run a chronic course, lasting for years.

Keloid is a connective-tissue new growth, consisting of one or more irregularly shaped patches or tumors, variously sized, reddish, smooth, elevated, firm and elastic. The lesions may be the size of a pea, a bean, or a finger; in shape elongate or ovoidal, firmly seated in the skin, and presenting a smooth, glossy surface, of pinkish, more or less variegated color. The form is generally peculiar, consisting of a body with diverging processes, not unlike a spider or a crab. Its growth is slow, occupying years, and the tumor is seldom painful except on pressure. Cases in which the lesions develop after burns are sometimes exceedingly painful. Respecting a cause, keloid may be divided into two varieties—spontaneous, in which it develops without any apparent cause, and cicatricial, where it develops after injuries, as burns, cuts, and severe flogging. It is also noticeably more common in the colored race.

Pathologically, the lesion is situated in the corium, and consists of dense fibrous tissue made up of closely packed fibres like cicatricial tissue. According to some, the change begins in the walls of the bloodvessels. The diagnosis offers no difficulty.

Treatment is, as a rule, unsatisfactory. The more the knife is used the more the disease spreads; it almost invariably recurs after operation. According to Vidal, repeated scarification is useful. Wilson recommends diachylon plaster, and in some cases it gives fair results. The growth sometimes disappears spontaneously.

Molluscum fibrosum is a connective-tissue new growth, sessile or pedunculated, soft or firm, rounded and variable as to size. It is single or multiple, the lesions being usually numerous, about the size of a pea, and grow upon the general surface, especially the trunk. They may begin at any age, grow slowly, and, having attained the size of a pea or cherry, remain stationary. There is no pain or annoyance attending their development. The cause is unknown. The disease is, however, apt to appear in individuals of a sluggish temperament, in those who are dull, and exhibit little physical or mental energy. The tumors consist of a whitish or yellowish fibrous tissue, being denser and compacter about the base. They cannot be enucleated, being firmly bound down to the subcutaneous connective tissue. The disease takes its origin in the connective tissue surrounding the fat globules. It is to be distinguished from molluscum epitheliale and sebaceous tumor, also from lipoma. The treatment, when the lesions are not too numerous, consists of extirpation with the knife, ligature or galvano-cautery.

Xanthoma is also a connective-tissue new growth, which has of late excited attention, especially in England, where the disease seems to be most frequently met with. It is characterized by yellowish, circumscribed, irregularly shaped, soft, flat or raised patches or tubercles. There are two varieties, which clinically are entirely distinct,—xanthoma planum and xanthoma tuberosum. The lesions are in the corium, and the patches have the look in the flat variety of being inlaid, resembling pieces of chamois-skin laid in the skin. They are usually met with about the eyelids, in the form of narrow semicircular patches, sharply defined, of a pale or dark buff or lemon color, and may extend from one canthus to the other. They give rise to no pain or inconvenience, but may give the individual a grotesque appearance.

The tubercular form consists of pin-head, pea-sized or larger tubercles, usually of a golden-yellow color, occurring on the neck, trunk and extremities. It is a disease usually of middle life, but is exceptionally met with in children. The lesions may be single or multiple. The multiple form (xanthoma multiplex) is rare. They develop as a rule gradually and pursue a slow course.

The causes are not known. It has been supposed that the disease has some connection with hepatic disorders, and this is sometimes the case in the multiple variety; xanthoma palpebrarum, on the other hand, is seldom connected with jaundice. The disease is more common in women than in men. Pathologically, the growth consists of fattily degenerated connective tissue. The treatment is excision, which in suitable cases is usually satisfactory. Spontaneous involution occasionally occurs.

Rhinoscleroma is a rare disease, chiefly encountered in Germany, consisting of a circumscribed, irregularly shaped, flattened, tubercular, remarkably hard and dense, cellular new growth, having its seat about the nose. It is unknown in this country, no typical case being as yet reported.

Lupus erythematosus is a cellular new growth, characterized by variously sized, rounded or irregularly shaped, more or less inflammatory, scaly patches, having its seat usually about the face. The disease generally begins as a small, insignificant, reddish patch, with slightly adherent scales, increasing gradually in size from week to week or month to month. Later, new lesions spring up. They are pale or deep red or of a violaceous tint, having usually a well-defined border, slightly elevated, and covered with yellowish or grayish, sometimes sebaceous, scales. The latter are attached to the openings of the sebaceous glands, which are distended by plugs of sebaceous matter. Sometimes the patches grow rapidly with inflammatory symptoms. There is also, at times, heat and itching. One, two or more patches are usually present, and the region generally attacked is the face, especially the nose and cheeks, the lesions often assuming a butterfly form. The affection runs a chronic course, it may be for years, spreading, and in some instances disappearing from time to time, leaving soft, whitish, superficial, more or less punctate, atrophic scars. It is by no means a rare disease, and is rather more frequently encountered in women than in men. It seldom appears before adult age, and in this respect differs from lupus vulgaris. It may develop from a simple congestive seborrhœa; in other cases the causes are obscure. It is a combined process, consisting of an inflammation and of a new growth. It often begins in the sebaceous glands, also sometimes about the sweat glands.

Microscopical examination of recent lesions reveals aggregations of small round-cells around the follicles and glands, together with other inflammatory changes. Later stages show retrograde changes in the tissues which lead to absorption and atrophy. If the retrograde metamorphosis takes place early, no cicatricial tissue is found, and no trace of the lesions remains.

The diagnosis is, as a rule, easy; the regions affected, the sharply defined patch with border, the adherent, yellowish scales, and the involvement of the sebaceous glands, are all important differential points, and serve to distinguish it from lupus vulgaris, syphilis, psoriasis and seborrhœa. The disease is generally obstinate, but in the inflammatory types should not be treated too actively, as with caustic remedies, at first. Internally, iodine is valuable in some cases in the form of iodized starch, as recommended by McCall Anderson, consisting of twenty-four grains of iodine, triturated with water, and one ounce of starch gradually added. This is given in drachm doses. Iodide of potassium, cod-liver oil, and arsenic are also of value in some cases, especially when there is impaired nutrition. External treatment, however, usually gives the best results. In mild cases, sapo viridis, used in the form of plaster, or in combination, two parts to one of alcohol, used as a lotion, is an efficient agent. When there is seborrhœa, sulphur ointment may be used. In the superficial variety, the following is valuable:

℞.—Zinci sulphatis,
Potassii sulphureti, . . . āā ℥jss.
Aquæ rosæ, ... f℥iv.—M.

Sig.—Shake. Apply several times a day, five or fifteen minutes at a time.

Mercurials, carbolic acid, and tar are also of value. Tincture of iodine and glycerine, as recommended by Hebra, are at times useful. The following mixture will sometimes prove of service:

R.—Ol. cadini,
Alcoholis,
Saponis viridis, ... āā ℥ss.—M.

Sig.—To be rubbed in morning and evening.

Caustics should be used with caution. A useful method of treatment is that by scarification, multiple or linear, whether in the deep-seated or superficial variety. The prognosis should always be guarded.

LUPUS VULGARIS is a cellular new growth, characterized by variously sized and shaped patches of a reddish or brownish color, made up of macules, papules or tubercles, the disease usually terminating in ulceration and cicatrices. It generally begins in the form of small, grouped or disseminated points in the skin, of a yellowish or brownish color. These coalesce, forming patches of various sizes. They may also develop into papules and tubercles, the condition being then known as *lupus tuberculosus*, a common form of the disease, the lesions being rounded, defined, and varying in size from a pin-head to a split pea. The tubercles may then undergo absorption, leaving a desquamative surface (*lupus exfoliativus*), or ulceration causing destruction of tissue (*lupus exulcerans*). The ulcers may also be the seat of excessive granulation (*lupus hypertrophicus*). The disease appears, as a rule, in childhood, running a chronic course, persisting even throughout life. It attacks the face, as a rule, especially the nose, upper lip, and cheeks; also the ears, hands, and even the mucous membrane of the mouth and larynx, often producing much destruction of tissue, and, through the formation of extensive cicatrices, ugly deformity. Little can be said respecting the cause. It is related to the condition known as scrofula, and generally begins before puberty, differing in this respect from lupus erythematosus. It is rarely hereditary, and attacks both sexes equally. It is rare in this country, but is common in southern Europe.

The disease is sometimes met with in connection with scrofula, but in many cases is distinct from this disease. Pathologically it is a chronic inflammatory process characterized by a small-cell infiltration, tending to form in groups, and having its primary seat in the corium. These cellular groups are called by Kaposi "lupus nodes." Giant cells are also occasionally encountered. The combination of lupus and epithelial cancer is occasionally met with, the cancer developing from the rete and glandular elements of the skin long affected with lupus. It must be distinguished from syphilis, cancer, lupus erythematosus and acne rosacea. From syphilis, it may differentiated by the character of the ulcer, its slow, chronic course, slight, inoffensive discharge, and scanty crust. The cicatrices are moreover hard, irregular and yellowish, while in syphilis they are soft and whitish. From cancer lupus is easily distinguished. Cancer is as a rule localized, circumscribed, painful, indurated, and is accompanied by great destruction of tissue; it is furthermore a disease of later life. Lupus erythematosus occurs after puberty, is never accompanied by tubercles or ulceration, and shows usually disorder of the sebaceous glands, which last is not the case in lupus vulgaris. From acne rosacea, it is distinguished by the history of the lesions and by the dilated bloodvessels and the pustules.

Regarding treatment, the disease will always be found obstinate, and usually nothing short of heroic remedies yields good results. Internally, iodide of potassium and cod-liver oil are valuable remedies. External treatment is, however, most important, and a large number of remedies have been recommended, most of them being of a stimulating or caustic nature. In the early stage of the process stimulating applications, such as equal parts of iodine and glycerine, mercurial plaster, and tarry lotions and ointments, may be employed with a view of bringing about absorption. In a majority of cases caustics will have to be resorted to, and the ones most generally used are nitrate of silver in stick form, pyrogallic acid, carbolic acid, caustic potassa, chloride of zinc, and arsenic. One of the most valuable methods of treatment is that by erasion with the curette. Scarification, multiple or linear, is also highly useful; it must be repeated at intervals, and it will be noted that the lesions grow a shade paler after each operation.

SCROFULODERMA.—Under this term are designated those cutaneous changes which manifest themselves in strumous or scrofulous subjects. The most common lesion is the scrofulous ulcer, which is a degeneration of the skin resulting from the ulceration of an underlying lymphatic gland. Such an ulcer is usually elongate, of a violaceous or pinkish color, with an uneven surface, undermined here and there, and exhibits little tendency to undergo reparative change. Another lesion is the variously sized, irregularly shaped, yellowish flat pustule, met with upon the trunk and extremities, running a chronic course and leaving superficial scars. Another and rarer form is the fungoid variety, appearing perhaps most frequently about the extremities, especially the hands.

The treatment consists in the administration of such remedies as cod-liver oil, sulphur, iodine, phosphorus, and lime. Locally, stimulating ointments are indicated, and above all the use of the curette, as in the treatment of lupus vulgaris.

ORIGINAL ARTICLES.

ON SO-CALLED ABSCESSES OF THE FRONTAL AND MAXILLARY SINUSES, AND ESPECIALLY ON THE VALUE OF PERCUSSION AS A MEANS OF DIAGNOSIS,

AND THE PROPER OPERATIVE MEASURES FOR THEIR RELIEF.[1]

BY W. W. KEEN, M.D.,

PROFESSOR OF SURGERY IN THE WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA, SURGEON TO ST. MARY'S HOSPITAL, ETC.

I HAVE used the term "so-called abscesses" as, properly speaking, these are not strictly abscesses, but accumulations of pus in normal cavities. But the term, though loosely used, is perhaps the briefest and best, and is not really likely to lead us astray.

Both of these cavities are lined by continuations of the mucous membrane of the nose, and as is natural, therefore, one *cause* of such abscesses is

[1] Read before the Philadelphia Academy of Surgery, June 2, 1884.

a chronic or occasionally an acute nasal catarrh. Indeed, it is surprising that such results are not more frequent in view of the very numerous cases of the latter malady, whether as a chronic nasal catarrh, or as in the ordinary acute "cold in the head." In the latter the frontal sinuses especially are very frequently involved, as is shown by the frontal headache and the sudden and abundant escape of thick, ill-smelling, greenish discharge. That abscess of the frontal sinus is so rare is probably due to its effective drainage by gravity, as well as to the size of the infundibulum. In over twenty years of active practice I have seen only the two cases here recorded, and Dr. Harrison Allen, who saw the first case with me, informs me that in his extensive experience with nasal catarrh this is the only case he too has seen.

Another cause of abscess in the antrum is dental caries, or alveolar abscess. According to Salter, this is the most frequent cause of antral abscess, and this view is sustained by the number of cases recorded by him, and by Garrettson, Jourdain, and other dentists.

Sometimes mere closure of the orifices of these sinuses is sufficient to cause abscesses, by the want of proper "ventilation" of the sinuses, the retention and decomposition of the secretion and subsequent irritation. But this closure is usually merely due to tumefaction of the mucous membrane consequent upon catarrhal inflammation.

Traumatism may also occasionally be assigned as a cause; both accidental, as from blows and such like accidents, or surgical, as *e. g.*, Langenbeck reports two cases following resection of the infra-orbital nerve (*Archiv klin. Chir.*, xi., 1869).

In the frontal sinuses, though occasionally in the antrum also, especially in tropical climates, the larvæ of insects are sometimes causes of abscess, as is mentioned by Allen, Hyrtl, Dumesnil, Bordenave, and others. Galezowski[1] reports one curious case caused by a small splinter of wood in the root of the first left molar, which had been long carious. Low fevers also have occasionally produced such abscesses; occasionally also syphilis.

The *symptoms* are both local and constitutional. The constitutional symptoms are alike in the two disorders, chill, fever, thirst, sleeplessness, etc. But it is to be noted that they may be, and generally are, entirely absent, especially if the case is subacute or chronic, as in both of the cases recorded hereafter. On the other hand they may be of exceptional severity, as in the case recorded by Dr. Muir, of Madras (*Edinb. Med. Journ.*, 1866), in which death occurred in sixteen days from intra-cranial suppuration and epilepsy. Foucher and Van Boeneck also have reported fatal cases.

The local symptoms will vary according to the sinus involved. In abscess of the *frontal sinus* there may be pain in the forehead, often neuralgic in character, and following the nervous branches; a feeling of stuffiness in the head and nose; profuse or more frequently only moderate discharge of nasal mucus and pus. The mechanical symptoms will often predominate; sometimes, as in the case below, to the exclusion of the others. The pus will gradually increase and will cause either expansion of the cavity or perforation of one of its walls. The expansion may be bilateral if there be no partition between the two frontal sinuses, or unilateral if the septum be complete; exophthalmos may possibly result, as shown by Salter and Soelberg Wells. If perforation occur, it may penetrate either of the three walls. Most frequently it will penetrate the thin roof and bore into the anterior fossa of the skull and may cause meningitis; or it may penetrate the floor and so escape into the orbit, the site of the orifice being in some cases far back in the orbit; or, thirdly, it may open anteriorly above the eyebrow. It should also be remembered that openings may exist in any one of these situations, either as a result of atrophy or of faulty development, as has been best shown by Zuckerkandl. These most frequently exist in the orbital roof. If such perforations occur under the external skin, the escaping pus will form small and gradually enlarging soft tumors, reducible by pressure or by recumbency (an important point) and showing fluctuation if of any size. The character of the contents can then be easily determined by the hypodermic syringe or the exploring-needle. They may readily be mistaken also for sebaceous or other small cysts, or for tarsal or orbital tumors, an error easily corrected by attention to the points just mentioned.

In abscess of the *antrum* the pain is deep-seated and is apt to be referred to the teeth and the cheek, though it may sometimes radiate to considerable distances; a sense of fulness is perceived; if the nasal orifice is patent, pus will escape from the nose, and it is to be observed that it escapes from only the affected nostril, and if that nostril be cleansed and the patient lie upon the sound side, it will readily refill. If the roots of the first and second molar penetrate the antrum, as is not infrequently the case, the pus may escape by this easy channel and may destroy one or both of these teeth, thus transforming what is a frequent cause of the disorder into an effect. But if the pus be pent up, distention will also occur here, ending finally in perforation. If the orbital floor yield most readily, exophthalmos and even permanent amaurosis may result, as in Salter's notable case. The pus may even pass by the ethmoidal cells and orbit into the cranial cavity, as in the cases of Foucher and Van Boeneck already referred to (Bousquet, op. cit.), or it may push down the roof of the mouth, or push out the anterior wall forming the cheek. In all these cases great deformity exists, both from the distention of the bone and the inflammatory swelling and œdema of the soft parts; and if the pus escape through the cheek, instead of the mouth, unsightly depressed cicatrices result. With distention of the anterior wall comes also marked thinning of the bone, so that it will often crackle like parchment, and fluctuation may be perceived. Such swellings may be even mistaken for malignant diseases, and Heath, Agnew, and Broca mention cases of removal or impending removal of the jaw for a disease perfectly amenable to simple operative treatment.

The *diagnosis* of such abscesses is in general fairly easy, based upon the symptoms already stated, but

[1] Bousquet, Etude sur les abscés développés dans le sinus maxillaire, Paris, 1876.

one means of diagnosis that has served me a good turn I have not found mentioned in any of the text-books or special treatises I have consulted, viz., *percussion*. Even in the frontal sinus, if the median septum be complete, percussion will give an appreciable difference of tone on the two sides, the affected side being of course the flatter of the two; but in the antrum this is unmistakable to a practised ear. In fact, as will be seen, the diagnosis in the second case to be related was based largely on this physical sign. Of course, it would not assist us to diagnosticate between an antrum filled with pus and one filled with a cyst or a solid tumor, but taken in connection with the other symptoms present, it will go far to make certain that which is already probable. The operative treatment will be discussed later.

Case I.—Abscess of the frontal sinus, resulting from chronic nasal catarrh; perforation of orbital roof anteriorly; operation; cure.

Rev. Dr. W., æt. 54, for many years a sufferer from nasal catarrh and asthma, about two and a half years ago, casually called my attention to a small tumor as large as a large pea, just below the inner end of the right eyebrow, which he stated had existed for some months. Examining it very hastily, I judged it to be a small sebaceous tumor and told him if it enlarged any to consult me again when, if need be, I would remove it. I saw him at frequent intervals, and a year or so later observed that it had enlarged slightly and was becoming a mechanical obstacle in opening the eye. He then told me he had repeatedly observed that on rising in the morning it was not perceptible and only reappeared a short time after assuming the erect posture. I found that steady pressure would cause its disappearance in a few seconds, when the finger perceived an opening in the frontal bone about one-third of an inch in diameter, immediately below the inner end of the supra-orbital ridge. Percussion also showed a slight difference in the sound over the two frontal sinuses, the right being slightly duller. He had had for a long time a moderate and somewhat offensive nasal discharge from his nasal catarrh, but no increase recently, and no blood had been observed. Of late there had been a feeling of fulness in the right frontal region, but no real pain or other marked discomfort, and no constitutional disturbance. In view of the physical signs and his chronic nasal catarrh, I then diagnosticated an abscess of the right frontal sinus; aspiration by a hypodermic needle confirmed the diagnosis by revealing the contents to be an offensive, thick pus. Dr. Harrison Allen kindly saw him also and confirmed the diagnosis and assisted me in the operation. On February 21, 1883, I gave him ether and laid bare the opening by an incision about half an inch long, which gave exit to about two drachms of pus. The probe showed that the right sinus was completely separated from the left by a septum, that it was about half an inch deep antero-posteriorly, and that the internal surface was bare of mucous membrane, a curious fact in view of the complete recovery without necrosis. By a grooved director, slightly curved, I bored a passage with ease into the nose, washed out the sinus with carbolized water, and carried a rubber drainage-tube through the upper orifice into the nose and as far as the opening of the right nostril, securing it in place by a thread. The nose was examined by the finger and probe and a small piece of dead bone was removed by the forceps. The bleeding was slight. Moderate reaction followed for a couple of days, the temperature rising to 100.2° and quickly subsiding. Considerable pus was discharged by the nose. The cavity was syringed thrice daily by carbolized water. At the end of three days, as the discharge had much diminished, a small bundle of horse-hairs was substituted for the rubber tubing, and these were gradually removed during the next five days, when a single hair was left. At the end of the second week this was removed, the discharge then having ceased. The opening closed in a day or two. From then till now, a period of sixteen months, there has been no further trouble, save the nasal catarrh, for which he is now under Dr. Allen's care. The nose, I should say, is very high and narrow and the walls in contact on the right side.

Case II.—Abscess of the right antrum, arising from a cold in the head; operative perforation of anterior wall; cure.

Mrs. A., æt. 36, a delicate woman of a nervous organization, while in the country during the summer of 1882, caught an ordinary "cold in the head," which persisted for weeks in a moderate form with a slight muco-purulent discharge. She consulted me for it in November, 1882, but it was so moderate that I gave her simple remedies and saw her but four times at my office from November, 1882, to March, 1883. As the "cold" still persisted and had rather grown worse, I now examined her with care. She complained of slight pain in the right cheek, extending toward the inner angle of the eye, with a sense of discomfort and fulness. The teeth were sound, and there was no toothache. The discharge was somewhat scanty in the morning, but at about ten o'clock daily she had a pretty free discharge, enough to soil about two handkerchiefs. It was muco-purulent in character, unmixed with blood. From this hour the discharge lessened and was scanty during the rest of the day; it did not waken her at night; the amount varied somewhat on different days. The symptoms of "cold" were limited chiefly to the slight pain and the discharge. The nose was not blocked so as to interfere with respiration, except when obstructed with the discharge. Posture influenced the discharge only slightly. There was no fulness of the cheek, no thinning of the anterior wall of the antrum, no swelling of the overlying soft parts, no deformity in the roof of the mouth or about the orbital floor. Percussion over the two antra, however, revealed unmistakable dulness on the right side as compared with the left. This could only be caused by the growth of a solid tumor in the antrum, or by an accumulation of fluid in a cyst, or of free pus. The history, physical signs, and symptoms all seemed to point to the latter, and accordingly I advised an operation for its relief.

April 5, 1883, after giving ether, I perforated the anterior wall of the antrum, between the bicuspid and the first molar teeth, with a carpenter's triangular "counter-sink," using the instrument found in the

ordinary set of tools that come in a hollow handle for household use. About a half ounce of non-fetid pus escaped. I then introduced a new Nélaton catheter and syringed out the cavity with carbolized water, till the water came away clean. Nearly all of the injection escaped by the nose, thus showing the antral opening to be patulous and explaining many of the observed symptoms. Nothing was used to plug the opening and thus to prevent food from passing into the antrum, but to attain this object the diet was restricted to milk.

The reaction was very slight, the temperature never rising above 99.4°. For six days the antrum was washed out daily in the same manner, using smaller catheters as the opening contracted; two days later the opening closed and solid food was then allowed. All the symptoms of the cold quickly disappeared and no trouble has been felt from that time till the present, a period of fourteen months. The cicatrix is not perceptible.

The value of percussion as well as of the hypodermic aspiration is sufficiently shown by the histories related, and it only remains to discuss the operative treatment.

As to the case of frontal abscess, it is not needful to say anything further; and in reference to the antral abscess, only the point at which it is desirable to puncture needs a few words.

A century ago Jourdain recommended catheterism of the antrum by the natural opening, but the commission appointed by the Academy of Surgery rejected the proposed operation as "difficult and uncertain," and more lately, Broca has confirmed the opinion that it cannot be done even on the dead subject. Still more recently Zuckerkandl[1] has proposed to penetrate by an artificial opening below the natural one, where only mucous membrane separates it from the nasal cavity. But such an opening is neither an easy nor a sure operation, in so narrow a cavity as the nose, especially if the side involved is the narrowest one; nor does it provide so effective drainage as the alveolar process or the anterior wall, where the suction of the mouth as well as gravity facilitates the escape of the pus. About the only advantage it has is that it avoids the possibility of the entrance of food into the antrum. But this is not a practical difficulty. Restriction of the food to milk for a few days avoids all danger; and, as a matter of fact, I find that no pains have been taken, or at least are recorded in the published cases, to avoid any such accident, and no mention is made of its having occurred.

Nearly all modern authors, as Heath, Garrettson, Agnew, Gross, Bousquet, etc., advise the removal of a tooth and penetration into the antrum through one of the sockets by a trocar or drill, care being taken that the force used at the moment of puncture shall not drive the instrument too far up and so wound the eye. If the first or second molar tooth be so carious as to be useless, so that it ought to be drawn anyhow, or if the disease arise from the tooth, of course it should be removed and its socket used as a route for the perforation, not however by a trocar or drill, but by the surgical engine, as stated by Garrettson, since this will penetrate readily, and no danger of wounding the eyeball can arise. The first or second molar should be selected, inasmuch as their roots are directly in contact with the floor of the antrum, and even may penetrate its cavity.

But if these teeth are sound or by treatment can be preserved as useful teeth, they ought in no case to be destroyed. To extract a useful tooth needlessly is little short of a surgical crime, as it inflicts an irreparable and serious injury. In such a case I would strongly advise the perforation of the anterior wall, either by the "countersink," which I used, or by the surgical engine. No special trephine is necessary. The operation is easy, effective, and harmless, and its results leave nothing to be desired.

PROSTATIC CALCULI;

THEIR PROBABLE CAUSES, WITH NOTES OF REMARKABLE CASES.[1]

By CLAUDIUS H. MASTIN, M.D.,
OF MOBILE, ALABAMA.

There are very few subjects connected with medical science, which are involved in more obscurity than calculous diseases; and none which prove of more interest to the practical surgeon. Renal and vesical calculi have, from the earliest history of our profession, offered a fertile field for pathological research; and those minute concretions which form within the follicles of the prostate gland—although differing in their chemical constituents, and manner of formation from urinary calculi—have proved especially interesting, since their true cause has, as yet, not been thoroughly understood.

These minute concretions being at first almost microscopic in size, gradually increase, yet rarely acquire any considerable dimensions; seldom becoming larger than an ordinary pea. Still they aggregate in considerable numbers, studding the follicles of the gland, or when increasing in size, they break down its parenchyma and collect in distinct cysts. They increase in size doubtless from a deposition upon their surface, and when not escaping from the follicles they induce absorption of the tissue by direct pressure, and thus come into contact, forming considerable numbers collected together in one or more distinct pouches. Usually we find several calculi, each seated in a separate duct; these are generally quiescent and give no evidence of their presence; doubtless they frequently escape along the ducts of the prostate into the urethra and the bladder, and are washed out by the urine. Again, numerous concretions increasing in size collect together in a cyst, attain quite large dimensions, light up considerable irritation and inflammation, produce severe constitutional disturbance, terminating in abscess with ulceration, and are discharged either through the rectum or the perineum. It is possible that sometimes they may find their way into the bladder, and if not discharged with the urine may become the nucleus of true urinary calcu-

[1] Read before the American Surgical Association, April 30, 1884.

lus: this, however, is not probable, since we seldom if ever find calculi having a phosphatic nucleus encrusted with the lithates.

The accepted opinion as to their formation is, they have their origin in an oval vesicle of a single wall of homogeneous membrane, which is occupied by a colorless, finely mottled substance, in the centre of which, a nuclear corpuscle occurs. Their mean diameter being about $\frac{1}{10\,40}$th of an inch, until gradually increasing in size, the envelope still being visible, the amorphous matter begins to be arranged in layers concentric to the cell-wall: still further on in their development, the vesicles gradually increase in size, until their diameter reaches $\frac{1}{200}$th of an inch, or even more, continuing to show the concentric layers, which are now more developed on one side than the other, seeming like so many repetitions of the original envelope, the intervals between the layers being occupied by a finely mottled deep yellow or red substance. There is, within them, a central cavity which corresponds to their external contour in form, being triangular or quadrilateral with rounded angles.

Such is their usual and normal appearance, from which however, there are numerous variations showing a change of form and internal arrangement which makes them seemingly to occupy an intermediate position between organic growths, and inorganic concretions: like the former they are vesicular in their origin, and in their gradual growth, which appears to take place chiefly from the dilatation of the vesicle and successive deposition in its interior; on the other hand, they simulate inorganic substances in their shape, in their tendency to become infiltrated with earthy matter, and in their disposition to pass into the condition of a dead amorphous mass of a deep yellow, almost black substance.

It is a little remarkable that their chemical composition varies in the various stages of their development, and is, at all times, widely different from either renal or vesical calculi. At first they consist of little else than animal matter, gradually acquiring, but only when in a state of degeneration, calcareous salts, which, according to the analysis of a number of chemists, and especially that of Lassaigne, is—in 100 parts—

Basic phosphate of lime	84.5
Carbonate of lime	0.5
Animal matter	15.0
	100

On the other hand, we find that vesical calculi have a distinct nuclei upon which crystalline and amorphous deposits—more properly termed by Dr. Vandyke Carter "submorphous structures"—settle, and become embedded together in a colloid matrix, thus forming calculous masses. We also know that, when we come to examine the chemical constituents of different collections of renal and vesical calculi, we find three-fifths of all calculi met with in adults, of all ages, are composed of uric acid and the urates; whereas not quite two-fifths are phosphatic, while only some three or four per cent. of the whole number are oxalate of lime. Three-fifths, then, are the products of urine abounding in an acid, of which they are the expression; the remaining two-fifths are the products of urine, generally alkaline, mostly ammoniacal, of which they are the result; being, as a rule, ammoniaco-magnesian phosphates. It follows, then, that the urates, the oxalates, and a few of the phosphates—those which are formed within the kidney—must be the result of certain constitutional derangements; whilst, on the other side, the mixed phosphates are produced solely within the bladder, and are a consequence, not of constitutional, but of local disease: this is usually a sequence of enlarged prostate in men who have passed the prime of life; that steadily progressive sequence of pathological changes incident to advanced life, which favors the formation of phosphatic deposits within the bladder. For whenever the outlet to the bladder is obstructed, and the urine retained, it rapidly passes into a state of decomposition, eliminating free ammonia which lights up and increases a cystitis; now alkaline pus is secreted in abundance, and when formed it quickly gives up its soda to the lightly held phosphoric acid of the acid phosphates of ammonia and magnesia of the urine, which earthy substances, held in solution only by an excess of phosphoric acid, are rapidly precipitated as insoluble phosphates. When the pus is changed by the action of the liberated ammonia—as above mentioned—it is, together with the mucus of the bladder, converted into an adhesive colloid medium, which cements together the insoluble ammoniaco-magnesian phosphates into a mass, and thus forms the ordinary phosphatic concretions found in the bladder.

Very different appear to be the causes which produce prostatic concretions: instead of being sedimentary, so to speak, the deposition of their earthy material is doubtless the result of a deranged action of a mucous membrane, not a consequence of absolute disease, but, more properly speaking, should be considered indications of a trifling derangement in the secreting functions of the gland itself: or, as suggested by Virchow, is the consequence of the dissolution of the elements of the prostate, furnishing a fluid which, by the gradual formation of deposits, produces these amyloid bodies—bodies closely analogous to the corpora amylaceæ of the nervous system.

As their chemical composition is so widely different from that of true urinary calculi, being chiefly phosphate of lime, a substance, which appears never to be deposited in an unmixed state from the urine, it is evident that we can always readily distinguish them from those of urinary origin.

Without, however, consuming time with the bibliography or literature of the subject, I desire to call attention to one or two remarkable instances of large prostatic concretions which have been placed on record, before I present to the Association the clinical history, together with the specimen removed from a case, which during the past month has occurred within my observation.

Perhaps the most remarkable example, of which we have any record, is the one reported by Dr. T. Herbert Barker, of Bedford, England; a description of which is to be found in the *Transactions of the Provincial Medical and Surgical Association of England*, vol. xv. new series vol 3. pp. 235–242.

The patient, a farmer's laborer, aged 26, called upon Mr. Barker on the 25th of October, 1843, suffering from complete retention of urine, with considerable pain in the urethra, and especially in the perineum. He had a fistulous opening in the under side of the penis toward the left, about three inches from its extremity, from which a purulent fluid was discharging: there was a deep-seated hardness discovered upon pressure of the perineum, and a distinct crepitation detected upon moving the mass from side to side, as if produced by the limited rubbing of calculi impacted together. A rectal examination revealed considerable enlargement in the region of the prostate gland, and a similar crepitation was also felt as far as the finger could be introduced. All that could be learned of his previous history was, that since childhood, when four years of age, he labored under incontinence of urine, which had continued to the present time, rendering him offensive to society, and causing him, long since, to abandon it as much as possible. Until recently he had never suffered any severe pain, nor had his urine ever found any other outlet save through the natural channel, although recently the fistulous opening had made its appearance.

Mr. Barker removed the mass of calculi through the ordinary lateral incision, to the left of the perineum; they proved to be twenty-nine in number, weighing collectively ℥iij, ℥iv, gr. j=1681 grains Troy.

This collection of calculi is put upon record as one stone, which is not absolutely correct, since the mass was composed of distinct calculi, twenty-nine in number, cohering together by curved faces and easily separated into distinct concretions. The mass measured four inches and seven-hundredths in length, being very much larger at one end than the other, the larger end occupying a cyst within the prostate, from which it extended forwards into and along the urethra. An analysis of the largest calculus, made by Dr. Golding Bird, shows it to be identical in composition with those concretions which are occasionally found in glandular structures, consisting of phosphate of lime with a rather larger proportion than usual of the ammoniaco-magnesian phosphate: clearly showing that it differed, in a measure, from the usual composition of pure prostatic concretions.

A similar stone, said to be of analogous composition, but with no definite history, is catalogued as Specimen No. 2148, in the extensive collection of Guy's Hospital.

The second largest concretion of which I have found any authentic mention is in the Museum of the Royal College of Surgeons of London—specimen marked H, No. 13. This, like the one of Mr. Barker, cannot strictly be considered a calculus, since it is composed of four distinct calculi, being regarded as a single one simply because the four portions—one large and three small—were coaptated by smooth surfaces, although separate within the prostate. According to Prof. Owen, this so-called prostatic calculus, composed of four pieces, and having articulating surfaces, was taken from a cyst within the prostate, which cyst communicated, through an opening, with the bladder, into which one of the calculi protruded about one-tenth of an inch. The weight of this quadrified calculus is 575 grains, and it cannot properly be called anything else than a secondary prostatic calculus, or calculi, since there was a connection between the cyst and the bladder cavity; and the analysis of Mr. Owen clearly proves it to be composed of salts deposited from the urine, and not of prostatic origin, being of mixed phosphates, with the urate of ammonia and carbonate of lime.

Quite a number of cases of large urethral calculi are on record, but as they were of either renal or vesical origin, and their chemical constituents purely urinary, they do not pertain to the subject under consideration, and hence I make no reference to them.

Mr. Crosse, of Norwich, England, who has given to the profession a most admirable "Treatise on the Formation, Constituents, and Extraction of Urinary Calculus," devotes some space to the consideration of prostatic concretions; and, although mentioning several instances of large vesico-urethral calculi, does not speak of any case analogous in size or composition to the one mentioned by Mr. Barker, or the specimen in the Museum of the College of Surgeons. In fact, the cases he speaks of are not true prostatic formations, but rather what I am pleased to term secondary prostatic calculi, being vesico-urethral, and due to the arrest of small stones in the prostatic urethra during their transit from the bladder; all of them being composed of mixed salts, conclusively showing them to be of urinary origin.

Hence, not having been able to find on record an instance in which a single stone (one which a reliable analysis shows to be of prostatic origin), giving the size and weight of the one I now propose to present to the Association for inspection, I have thought it would prove interesting if I briefly furnish its history:

C. E. H., aged 46, a merchant by occupation, of fine physique, born in Mississippi in 1838, went to Virginia when but a child, and has resided in that State, at Wytheville, since his infancy. Of good general health in youth, his first trouble began in 1855, when, at the age of seventeen years, he contracted a blennorrhagia, which proved persistent, yielding only after a long course of stimulating injections; from this time on he had no trouble as a consequence of his disease, until the winter of 1864, at which time, whilst in the army, he experienced some difficulty in urinating, especially after long and fatiguing marches; this continued until the fall of 1865, causing him to resort to dilatation of the canal, which gave him measurable relief, and he married four years after, in 1869. His first child was born in 1871, and a second in 1875. Soon after this date he again noticed difficulty when he attempted to pass his urine, and an examination showed that a stricture had formed, which would not yield to dilatation; his general health had been failing since 1873, and after the birth of his child in 1875 he had no more children, notwithstanding his sexual desires were unabated, and his wife in robust health. In 1877 he was first taken with absolute retention, and it was found impossible to introduce any instrument into his bladder, and the only relief which he obtained was from the free use of opium, hot hip baths, poultices, etc. After this attack of retention he had constant stillicidium of urine—the overflow of a distended bladder; this caused him to seek the advice of a surgeon of Baltimore, but without relief, the stricture proving impermeable

to instruments, and he unwilling to submit to the operation of an external section. His health was now gradually failing, and during the year 1883 he was forced to retire from business, and measurably to exclude himself from society on account of his condition, being compelled to wear a urinal both by day as well as by night. In this condition he came to Mobile, in the early part of January of the present year, for the purpose of having me perform any operation which would possibly afford him a chance of relief, giving me the history which I have briefly told.

Examining his condition, I found him nervous, dispirited, a confirmed dyspeptic, generally broken down in constitution, although his habits were good, and he informed me he had never been intemperate. There was no history of any serious attack of illness, or of gout or rheumatism in his family; he had resided nearly all his life in a locality where hard water is drunk, and this may have been one, if not a chief factor of his dyspeptic condition, of his obstinate constipation, and the slight attacks of "bilious derangement" which he told me he was subject to.

A urethral exploration revealed a contracted meatus, and a canal narrowed from a normal calibre of 30 mm. to one of 25 mm., to the bulbar region, at which point I encountered a dense firm coarctation, through which it was impossible, by any manipulation which I could bring to bear, to pass the smallest size whalebone bristle. Not being in a condition to undergo an operation, I concluded to put him under a course of treatment calculated to brace up his general health, and when able to stand it, I would perform external perineal urethrotomy without a guide; it was not, however, before the 4th of March following that I found him in a condition for the same; and on that day he was placed under the influence of an anæsthetic, and in the usual cystotomy position. I then introduced a small bristle guide down to and into the coarctation, with the hope of being able to glide upon it a tunnelled staff, which would enable me, with precision, to open the urethra directly upon the face of the stricture. This I was unable to do, for although the guide passed into the stricture, when it reached the prostatic portion of the canal, its passage was arrested, and the presence of the stone at once made manifest. I had not then suspected any complication of the kind, and even after the stone was touched I naturally concluded it was only a small vesical concretion which had been arrested in the sinus of the prostate; for I had carefully examined this body through the rectum, which, with the exception of an unusual degree of hardness, gave no other evidence of any foreign body being contained within it. Unable to effect anything with the guide, I cut directly down upon the point of the staff, in the median line of the perineum, trusting to my knowledge of the anatomy of the region in opening up the membranous urethra to the apex of the prostate. I thought I would be able to extract the calculus and complete the operation, as is usual in cases of perineal section. In this I was foiled, for a careful examination now revealed the fact that the concretion was large and solid, filling the entire central portion of the gland, from which I was unable to remove it with the forceps, and was compelled to extend the incision downwards to the base of the prostate, and with two fingers in the rectum dislodge the stone, as after the old method of cutting upon the Gripe. After its removal I made a careful digital examination of the cavity, which it had occupied, and found the gland structure almost gone, a cyst remaining, which seemingly was limited only by the capsule of the gland; the opening of the urethra into the bladder was not enlarged, nor was there any abnormal opening into that viscus. A little pressure enabled me to pass my finger into the bladder and explore it thoroughly: there was no contraction of its walls, and no appreciable diminution of its normal size, which somewhat astonished me, as it is usual in those cases in which the inner mouth of the urethra is obstructed, causing an arrest of the urine, with constant stillicidium of the same, to find the bladder walls thickened and its cavity lessened in size.

The patient reacted well—although at first he bore the anæsthetic badly—and went on to a favorable convalescence, the wound having almost healed, and he expressed himself as being vastly more comfortable than for fifteen years past; when, unfortunately, on the 19th, fifteen days after the operation, he indulged his fancy in a bowl of stewed dried peaches, which produced a violent attack of cholera morbus, which in his enfeebled condition speedily passed into collapse, and he died within twelve hours.

The calculus is very like, in size and shape, a normal adult prostate, it being, in fact, a perfect casting of the expanded cavity of the gland; and, from its chemical composition I feel justified in believing, had its origin first within a follicle of the gland, and, escaping into the sinus pocularis, became arrested, and from continual accretion attained its present size, producing, by its pressure, gradual and regular absorption of the gland itself.

Its weight is ʒvij + grs.x—or, in round numbers, 430 grs. Troy; a concretion of very fair average, even for a bladder stone, and one which ranks among the largest of single prostatic calculi. Fragments which were broken off in the attempts to use the forceps for its removal, were sent to Prof. T. G. Wormley, of the University of Pennsylvania, who carefully examined them, and wrote me as follows: "I find it composed entirely of calcium phosphate, or *phosphate of lime;* the specimen is a very interesting one."

As will be seen upon inspection, the stone has not been sawn open, and hence I am unable to say what the nucleus is; but from the constituents of its cortical portion, and its concentric and regular layers, I feel very well assured that the concretion is one purely prostatic in its origin.

Daily Record. March 5.—8.30 A. M. Patient rested well last night, and expresses himself as feeling very well, indeed. His urine is passing *via* both the urethra and the wound. Pulse 96; temperature 98⅘°. 5 P. M. Has spent a quiet day; comfortable; his urine still passing in normal quantity, and very much clearer than before the operation. Pulse 92; temperature 100⅕°. Doing very well.

6th.—11 A. M. He rested very well last night, and general condition is good. He had a natural

action from bowels this morning, and from a little swelling of the wound, the most of the urine passes along the urethra. Pulse 96; temperature 100°. Doing very well. 6 P. M. No change in pulse or temperature; has spent a comfortable day.

7th.—11 A. M. He slept quietly all night; had some desire for food, and said he would fancy a little port wine. Had a good, free action from bowels, and was very comfortable. Urine passing both ways, but more through urethra; this is due to the slight swelling of the wound. Pulse 96; temperature 100⅔°. 6 P. M. He has been doing very well all day, and says he feels extremely well. Ate more than any day since the operation, and took about ℥iv of port wine. This, doubtless, ran up his pulse and temperature, although general condition is good. Pulse 100; temperature 101¼°. Ordered calomel, gr. j; sugar, grs. x—at bedtime; also, ℈jss of bromide of sodium.

8th.—11 A. M. He spent a very comfortable night; slept well. Calomel operated well. He is passing urine at will, through both wound and urethra. Some slight suppuration of wound. Pulse 92; temperature 92⅔°. 6 P. M. No change of condition; expresses himself as very comfortable. Ordered bromide of sodium, ℈jss, at night.

9th.—10 A. M. Slept well; very comfortable. No action from bowels this morning. Urine passing at will, through wound. General condition good. No urine passing save when he has the desire. 4 P. M. This afternoon he is doing well, but there is more heat and rise of pulse. He ate some cooked oysters, which did not agree with him so well. Pulse 96; temperature 101⅕°. Ordered bromide at night.

10th.—9 A. M. Not so well this morning; no action from bowels since 8th. Says he feels very well, but languid. Pulse 104; temperature 101°. Ordered calomel, gr. j; sugar, grs. x. 4 P. M. Very little change in condition; no action as yet from calomel. Left him to await action of calomel, and then take his bromide at bedtime.

11th.—9 A. M. Calomel acted very well. He slept quietly; feels very much better this morning. Pulse 100; temperature 99⅔°. Ordered light but nourishing diet, and quiet. 5 P. M. Spent quiet, comfortable day, and is feeling very well. His general state is good. Temperature almost normal; pulse 90. Urine passing *via* the wound at his efforts to micturate, but the greater portion passes the normal way. The wound is closing, with healthy granulations, and shows some slight pus secretion.

12th.—He is doing so well to-day that I told him he could sit up in arm-chair, as a rest, if he desired it, and that I would not make the regular afternoon visit.

13th.—Still doing well. Slept well; very much better. Almost all the urine passing per urethra, and he expresses himself as so much better than for years past that he hopes to be perfectly well again.

14th.—Patient steadily improving, and from this date on to the 19th, the case record shows nothing worthy of mention. On the afternoon of the 18th, he was doing so well that I informed him there was no necessity for me to make stated visits, and that I would caution prudence and care, and that he would soon be in a condition to return home. The sequel has been told; an indiscretion in diet brought on the attack of cholera morbus which closed the scene.

THE PATHOLOGY, ETIOLOGY, PROPHYLAXIS, AND TREATMENT OF PUERPERAL FEVER, FROM THE VIENNA STANDPOINT.

(Concluded from vol. xliv. p. 468.)

By W. W. JAGGARD, M.D.,
ADJUNCT PROFESSOR OF OBSTETRICS IN THE CHICAGO MEDICAL COLLEGE.

IV. Treatment. In the event of systemic infection, treatment is of a general and local character. General treatment is symptomatic. The cold-water bath, ice or wet-pack, rectal irrigation, quinine, sodium salicylate, and alcohol are the only reliable antipyretics.

The cold-water bath is employed, as indicated by Liebermeister in 1871, in sthenic cases, when the fever is intense and of long duration. The patient is placed in the bath, with the water's temperature at or below 20° C., allowed to remain ten minutes, removed without drying, and wrapped up in bed. Upon withdrawal from the bath, a glassful of wine, or other mild stimulant, is usually exhibited. A cold bath of brief duration is more effective in the reduction of temperature than a longer continuance in warmer water.

The gradually cooled baths of Ziemssen, in which the temperature of the water is gradually lowered from 35° C. to 22° C., is useful in asthenic cases. Cold wet-packs are well borne by the feeblest patients, especially when the feet and legs are not covered.

Four wet-packs, each one lasting from ten to twenty minutes, in succession, are about equivalent in effect to one cold-water bath of ten minutes duration. Ice-bags, applied to the inguinal regions, are important adjuvants to the wet-packs. Cold sponging, compresses, ice-bags, drinks, enemata, are ineffective when employed to the exclusion of more positive means.

Continuous irrigation of the rectal mucous membrane, with cold water, by means of a double tube, is an effective measure in the reduction of temperature.

Quinine is exhibited in conformity with Liebermeister's views, that in persistently high temperature, it is only then of decided antipyretic action, when given in large doses, 1½ to 2½ grammes, in the course of one-half to one hour, not repeated within forty-eight hours. According as the first dose has or has not effected reduction of temperature to the normal, the second dose, at the expiration of forty-eight hours, must be smaller or larger, respectively. Powdered digitalis, ¾ to 1½ grammes, exhibited, at intervals, during the second twenty-four hours, is reported to have an important adjuvant action, when the maximum first dose of quinine has been ineffective. When the fever is of a decidedly remittent, or intermittent type, the indications for quinine are decidedly less urgent.

Sodium salicylate is an effective antipyretic; it is usually better retained than quinine, and is very much cheaper. For these reasons, it is extensively employed in the Vienna Obstetrical Clinics. It is customary, in the beginning of puerperal fever, to administer 3 to 6 grammes of sodium salicylate, in divided doses, during twenty-four hours, and to continue this treatment until the temperature returns to the normal. When quinine and sodium salicylate are not retained by the stomach, they may be exhibited, upon the addition of a little opium, by the rectum, in the form of clyster or suppository, with very slighly diminished physiological action.

Digitalis is seldom employed as an adjuvant antipyretic, while veratrin and *eucalyptus globulus* have received positive condemnation, the former, as dangerous in affections of a distinctly adynamic type; the latter, as totally ineffective.

It has been conclusively demonstrated by extended clinical study that night is the time best adapted to the application of antipyretic agents. Not only is the full physiological action of therapeutic measures more easily established during this period, but also sleep, especially after midnight, is usually gained.

Alcohol fulfils numerous indications. It is an important antipyretic, analeptic, and dietetic agent. The researches of Binz, Breisky-Konrad, Schroeder, Spiegelberg, and Carl Braun go far to establish the truth of this statement. It limits metabolic activity, and consequently the formation of urea and carbonic acid.

"It has, in addition to the stimulant effect, a certain conservative action, and is, therefore, adapted to cases of cardiac debility or paralysis" (Braun).

Rum, containing about seventy-seven per cent. of alcohol, is an eligible form, as producing the maximum effect with the minimum dose. It may be given in teaspoonful doses, every half hour, alone in combination with quinine, or tea, constituting the favorite Continental beverage, "Russian Tea," according to indications. A good cognac, containing fifty per cent. alcohol, or average table wine, containing ten per cent. of alcohol, is frequently employed.

Buss (1878) proposed a fever diet, which has given great satisfaction.

The formula is:

	Grammes.
Beef peptones	100
Grape sugar	300
Cognac or rum	200
Water	300

This quantity of food is administered during twenty-four hours, and may be reinforced by milk, wine-soups, or the famous *bouillon* with egg.

A systematic plan of treatment, combining cold-water baths, wet-packs, quinine, sodium salicylate, and alcohol, is productive of happier results than exclusive reliance upon one or two therapeutic agents.

Considerable difference of opinion, as regards local treatment, exists at the present time in Vienna. As antiseptic methods have received greatest attention and achieved best results in Carl Braun's wards, his views and practice will receive exclusive mention.

In the beginning of puerperal fever, the vagina is thoroughly irrigated with a two to three per cent. solution of carbolic acid, and the vulvar, vaginal, and cervical wounds are treated topically with a five to ten per cent. solution of the same acid.

Braun's methods of treating the uterine cavity have undergone important modifications within the past few years. In the last edition of his work on gynecology, he joins with Olshausen in his protest against intra-uterine irrigation as an inefficient, meddlesome, and dangerous procedure.

At the present time, however, intra-uterine irrigation is invariably practised, immediately upon the completion of the third stage of labor, when indicated by *endometritis sub partu*, bad-smelling and discolored amniotic liquor, dead or macerated foetus, invasion of the cavity of the uterus by the hand or any instrument.

During the *puerperium*, the uterine cavity is irrigated when there is positive evidence that it is the source of infection. The antiseptic irrigating fluid is a lukewarm dilute solution of thymol; the quantity injected into the uterine cavity at one time is limited to one litre; the number of irrigations, in twenty-four hours, is determined by consideration of the individual cases, but rarely exceeds two.

Infinite care is taken to exclude air from the conducting tubes, and after each vaginal or uterine irrigation a *bacillus*, containing five grammes of iodoform, is placed within each canal.

Routine intrauterine irrigation, injection of carbolic acid or salicylic acid solutions, continuous irrigation with acetic clay (Brunz, 1878), drainage of uterine cavity (J. Veit, 1879), drainage of uterine cavity with ice-cold water (Schroeder, 1879), are methods of local antiphlogosis, which have received most decided condemnation.

Gentle friction, or massage, applied through the abdominal walls to the fundus, at regular intervals, aided by the binder and ergot, is of benefit, when not contraindicated by excessive tenderness upon pressure.

In cases in which a considerable area of the vulvar, vaginal or cervical expanse is involved in an ulcerative or gangrenous process, the continuous lukewarm water bath of Hebra is an invaluable method of treatment. Hebra's water-bed consists of an ordinary bath-tub, in which an iron frame is suspended by chains; upon this frame, suitably covered and provided with a pillow, the patient is placed; by means of a crank she can be lifted up out of the water and returned again, according to necessity. The bath is filled with water at a temperature of 30–31° C., and the patient, perfectly nude, is caused to descend until the water covers every portion of her body, except the head. The temperature of the water is then rapidly elevated to 38–40° C.

She remains in this bath day and night, except when withdrawn for the purpose of evacuation of bladder or rectum. The water is kept at a constant temperature, and is continuously renewed.

Weeks and months are frequently spent, with an extreme degree of comfort, in this water-bed. In the words of Billroth:

"The water protects the wound surfaces from con-

tact with the atmospheric air, prevents decomposition of the sphacelus, favors its separation; it makes every dressing, and every change of dressing, unnecessary; limits the secretion of pus, and hastens cicatrization."

MEDICAL PROGRESS.

Combined Version in Placenta Prævia.—C. Behm has used combined version in forty cases of placenta prævia, without a single death. This must be regarded as an extraordinarily good result for a condition which ordinarily gives a mortality of forty per cent. Hofmeier has already obtained similar results in the treatment of placenta prævia.

The operation is performed as follows: When dangerous hemorrhage comes on the vagina should be tamponed until the cervix is closed. This being done, and the woman anæsthetized, the whole hand is introduced into the vagina, and two fingers into the cervix. If the membranes present, the operator endeavors to rupture them with the finger, then draws the presenting part (unless it be the buttocks) to one side, at the same time making pressure from without so as to carry the buttocks down, until he can grasp a foot. This is drawn through the cervix, so that the breech acts as a tampon on the lower segment of the uterus, and the placenta is pressed against the sides of the uterus. In central implantation of the placenta, the finger should be pushed through the centre.

After this version the operator waits for the spontaneous expulsion of the child, or at least complete spontaneous dilatation of the cervix, in order to complete delivery. The duration of labor after version is between one-half an hour and eleven hours, the average being one or two hours.

The mortality for the children by this procedure is very great, but the chances for the mother are better. The mortality for the children is, however, no greater than by the old operation.

The causes of the great mortality of the mother under the use of the continuous tamponade is the infection through the blood and other matters adhering to the tampon.—*Centralbl. f. d. gesammte Therap.*, July, 1884.

The Physiological Effects of Kairine.—M. Morohovetz, of the University of Moscow, has recently made quite extensive experiments as to the physiological effects of kairine, and publishes (*Medicinsk. Obosrenie*, No. 9, 1884) the following results:

The physiological action of kairine is not simply confined to lowering the temperature. The changes which gr. $\frac{1}{85}$ of kairine will cause in the blood are enormous. In his experiments, Morohovetz used kairine dissolved in a six per cent. solution of common salt, so as to avoid the action of distilled water on the red globules. The blood remained alkaline, but its color changed as soon as a more concentrated solution was used. A continuous current of air deprived of carbonic acid did not restore the red color of the arterial blood. The blood-spectrum was also changed by the concentration of the kairine, and contained four methæmoglobine lines, situated between the C and F lines.

Under the influence of kairine, the blood-globules formed roulettes, at the same time that the middle part protruded from one side to the other. The number of globules does not diminish. The blood of a dog which has taken kairine coagulates almost immediately after it comes out of the vessels. Under the influence of kairine, the red globules of the blood, while preserving their quantitative proportion, undergo a quantitative and qualitative change in regard to the coloring matter; the hæmoglobine is transformed into methæmoglobine, which is precipitated. The change in the color of the blood of a living animal by cyanosis gives a peculiar leaden appearance. The same thing was noticed by Golouboff after the administration of gr. xj of kairine.

The glandular organs are also influenced by kairine. The saliva and bile flow more abundantly after kairine is injected into the blood, or introduced into the duodenum. The bile is viscid, and almost black. The pancreas and the kidneys are not influenced by kairine. It is eliminated by the kidneys, as shown by the action of fuming nitric acid on the urine; a bright reddish ring forms between the acid and the urine—a ring which is characteristic of kairine in an aqueous solution. When bile is normally excreted, this ring takes the spectrum colors, and the urine gives the greenish color-reaction of biliverdine.

The modifications of respiration and circulation are more rapid and pronounced as the quantity of kairine is increased. The direct injection of it into the blood causes an intense dyspnœa, accompanied by an elevation of arterial pressure in the carotid; this being followed by diminished pressure, shortening of the pulse-waves, and filiform pulse. After the ingestion of gr. xxv, the heart of the animal was arrested, and it died of cardiac paralysis, the respiration continuing for some time, and being of a Cheyne-Stokes character. At the autopsy, the cavities of the heart were found dilated and filled with blood. The classic experiment on the frog (ligature of a limb), showed that kairine acted similarly to curare on the peripheral ends of the motor nerves.

In experiments on dogs, Morohovetz found no notable abatement of temperature. The experiments of Filehne have shown that, to obtain a notable abatement of temperature, it is necessary to inject kairine continually; less than gr. iv produces no effect. But it is easy to exceed the required amount, and to throw the patient into such a state that his inspired oxygen is insufficient for his physiological necessities, as kairine deprives the hæmoglobine of a large quantity of its oxygen. Morohovetz terminates his paper by counselling great prudence in the administration of kairine; he considers pulmonary and cardiac affections, and anæmia as absolute contraindications to the administration of kairine.—*L'Union Méd.*, July 10, 1884.

The Risks of Corrosive Sublimate Injections.—The unfavorable cases are beginning to be reported of the use of corrosive sublimate, as what we know of idiosyncrasy leads us to expect in the use of any powerful remedy. In *Schmidt's Jahrbücher* (Bd. ccii, No. 4) some such instances are related. Professor Stadtfeldt, of Copenhagen, while admitting its efficacy in most cases, is yet evidently somewhat afraid of it, especially as entrusted to midwives during labor. In the puerperal state, he used it with excellent results in six consecutive

cases, but in the seventh the effect was as follows: The patient, a twenty-three year old primipara, had a retained placenta, which required artificial removal. Uterus and vagina were at once washed out with carbolic solution. Four days afterwards there was a chill, with temperature of 39° C. The next day a solution (1–1500) of corrosive sublimate was injected. After about 300 to 400 grammes of the solution had run out, the patient suddenly complained of headache and difficult breathing. Her replies were somewhat uncertain, but consciousness was undisturbed. Some pains came on in the hypogastrium; the whole lower abdomen was tender, but not swollen. After a time, a profuse sweating came on, and the pains ceased. There were heaviness, giddiness; stools thin; tenesmus; urine highly albuminous; no fever; temperature subnormal. In the course of the next day the most important symptoms were vomiting, thin stools, with tenesmus, great thirst, and headache. The fifth day after the use of the injection the urine stopped, the consciousness became clouded, and the patient died quietly on the next.

Of course, the cause of death was not at once certain, but an autopsy showed no peritonitis. Numerous ulcerations were found in the large intestine. The kidneys were much altered. Mercury could be detected in no organ. Stadfeldt considered it a case of death from mercurial poisoning.

In another instance a woman was operated upon for prolapsus of the vagina and rectum. During the operation, which lasted one hour and a half, the flaps were washed from time to time with a 1–1000 solution of sublimate. The next day the vagina and anus were washed with the same solution, which was also injected into the rectum. On the sixth day the patient complained of great pain in the mouth. The gums were seen to be inflamed. There was much salivation. The use of the sublimate was stopped, and vigorous treatment directed to the mouth, after which the symptoms vanished in a few days.—*Boston Med. and Surg. Journ.*, July 24, 1884.

New Treatment of Ulcer of the Stomach.—Simple ulcer of the stomach, the ulcer of J. Cruveilhier, which is often called the round ulcer, is one of the most rebellious affections to therapeutic measures. Why is it that this *simple* ulcer, as it is called, persists for months and years without cicatrizing? What cause presides over the formation of the ulcer, and what influences preside over its development, its chronic course? If one wishes to give to these questions a truly scientific solution, he is obliged to acknowledge that there is something connected with its origin and course, which is still unknown. The theories of thrombosis, embolism, and of inflammation, if they explain the losses of substance, and the ulcerations of the mucous membrane, do not explain the form and characters of the round ulcer. So far as the action of gastric juice is concerned, if it contributes to the progress and extension of the ulcer by a sort of digestion, why is this digestion limited so often, and not cause fatal perforation and destruction of the stomach. It would seem that the acid reaction of the gastric fluids has a bad effect, since so much good has been done by alkalines and Vichy water.

The treatment of these ulcers is a more simple matter than the pathogenesis. The beneficial effects of strict diet have long been recognized, especially of the milk diet. But there are serious objections to the milk treatment. A person with ulcer of the stomach should take, if put on the milk diet exclusively, three or four quarts of milk every day. This enormous quantity may be well tolerated, and the gastric pains, the vomiting, and hemorrhages may cease. But one cannot with impunity introduce into a sound stomach, much less into one in bad condition, four quarts of liquid a day, without causing dilatation of the stomach. Without doubt, this can be in a manner obviated if the patients be not allowed to take much milk at a time. But the morbid state and atony of the stomach make digestion more slow and difficult. If to this we add the fact this dilatation of the stomach may cause hemorrhage and perforation of the ulcers, it is easily seen that the milk diet may be a source of great danger.

For a long time M. Debove has paid special attention to means for reducing the quantity of milk ingested. For this purpose he has used concentrated milk and powders of milk, representing, in small volume, considerable quantities of milk. But these have not the nutritive value which is found in meat powders. It has been objected to M. Debove's theory, that the dilatation of the stomach which he attributes to the quantity of the ingesta is due to the affection itself, to the ulcer of the stomach. But, as Bouchard has seen, who has for a long time recommended a dry diet for dilatation of the stomach, and as Debove has also seen, the dilatation disappears under the influence of this regime alone, so that it cannot be due to the ulcer.

The dry diet of M. Bouchard consists in the administration of food very finely divided, or very divisible, as powdered meat or cheese, and at the same time very nutritive. While the amount of dry food is reduced, only a minimum quantity of liquid is allowed, about a pint of water, or wine and water, in twenty-four hours. On this diet the stomach is never distended by food, and the dilatation diminishes or disappears. It is by this dry diet that M. Debove treats ulcer of the stomach; but he adds an important factor to it. Before commencing treatment he washes out the stomach, in order to clear away the mucus, and the *débris* of food which may be there. This washing is done with a rubber tube by the physician himself, as a little carelessness in its use might cause hemorrhage. Duguet has reported a fatal case of hematemesis, caused by the patient attempting to use the tube himself. Debove has never had a case of hemorrhage attributable to the use of the tube, but he very justly remarks that hemorrhages are quite frequent in ulcer of the stomach, and that when the tube brings up "coffee-grounds" blood it cannot be said that the hemorrhage was caused by the washing. If, however, during the washing the liquid brought up has a rosy tint, the operation should be at once suspended.

M. Debove believes that if gastric digestion and the action of the gastric juice can be suspended for some time, the cure of the ulcer will be greatly favored. By rendering the gastric juice alkaline its digestive properties are taken away, and the transformations of albuminoid substances into peptones is stopped. In this manner the matters undigested by the stomach pass into the intestines with an alkaline reaction very favorable to intestinal digestion. Debove has obtained effects which lead him to believe that he can make a

patient take ʒvij of bicarbonate of soda, in three doses, in twenty-four hours. He has shown, by his washings of the stomach, that under the influence of this treatment, the stomach liquids were never acid, and contained no peptones. The patients were given ʒvjss of meat powder, and ʒijss of bicarbonate of soda three times a day. This mixture not being very agreeable to the taste, is introduced into the stomach through the tube. To this diet, which represents ʒlxx of meat and ʒvijss of bicarbonate of soda a day, is added a quart of milk, taken in small quantities during the day.

The *alkaline cachexia* which Trousseau and other physicians have spoken of was seen in none of Debove's patients. This treatment has given most excellent results; results which have never been attained by any other method of treatment.—*Le Progrès Méd.*, July 12, 1884.

Heteroplasty.—L. von Lesser, in an article on the retention of catgut in the organism, and on heteroplasty, gives the results of his experiments on the healing up of foreign bodies in tissues, and the filling up of tissues, and especially of bone cavities, with cork, gum, and lead balls (heteroplasty); he also made experiments in replacing tendons by elastic threads. In the insertion of such foreign bodies into trephine-openings in the roof of the skull and in the tibia, encapsulation only occurred when the wound was kept completely antiseptic; the cork being encapsulated much sooner than the gum. The greater number of the animals experimented upon died of sepsis. When the wound proceeded favorably the enclosed foreign bodies were found pressed out of the trephine-holes and encapsulated in the connective tissue, the trephine-holes themselves closed by a fibrinous membrane or diminished from the edge of the bone out through the marginal growth of bone. In case of sepsis the foreign bodies lay in abscess cavities, and were surrounded by caseous pus, the trephine-holes were surrounded by pus, and in one case had changed into pseudarthrosis. The fact that gum-plates healed up in laparotomy-wounds is one of gynecological interest, and upon which careful experiments were made. Caoutchouc plates were fastened behind the abdominal peritoneum with catgut, so that the posterior side of the plate was toward the peritoneal cavity and the anterior lying against the parietal layer; it was left in this position for a day. The skin over the plate was sutured deeply and superficially, the muscular structure being sometimes sutured, and sometimes not. With the exception of one case, which, in consequence of wounding the intestine, died of perforating peritonitis, the course of the wound was usually favorable, but sooner or later knotty tumors appeared behind the abdominal walls in the situation of the laparotomy wound, which were found to be abscesses with caseous contents. The caoutchouc plates were found, on post-mortem examination, to be enclosed in connective tissue, from the serosa out; a part of the intestine at the seat of the wound was for the most part enclosed by the anterior abdominal wall, whilst there were no symptoms of inflammation in the peritoneum; in one case there was gangrene of the testicles on both sides. Pus was found partly collected on the anterior surface of the gum-plate, and partly collected in the connective tissue all around the plate; in one it had burrowed down to Poupart's ligament.—*Centralbl. für Gynäk.*, June 21, 1884.

The Treatment of Sprain by the Elastic Bandage.—This method of treating sprains has recently been recommended by Marc Sée. It is the only method which fulfils the two indications: 1. To cause as rapid absorption as possible of the blood extravasated around the joint (a lesion which controls all the other symptoms, such as pain, swelling, difficulty of movement, etc.); and, 2. To favor cicatrization of the torn ligaments and ruptured parts by complete immobilization.

The antiphlogistics and bloodletting, formerly advised by Hunter and Guersant, only partially fulfil the former indication. There is the same objection to the movements which Ribe and Bonnet advise for the injured joint. The refrigerants and cold-water baths advised by Baudens cause contraction of the tissues around the joint, and dispel the inflammation, but they are not favorable to the absorption of the infiltrated fluids. Even massage, though superior to the other remedies just mentioned, fulfils only the second indication; furthermore, it is inconvenient, and requires much patience and time; and between the seances of manipulation the swelling reappears and the pain returns. It is true that massage has the advantage of removing the extravasated materials from the region of the joint toward the more vascular portions of the limb, where they are more easily absorbed. But the elastic bandage has this advantage in a greater degree, since its action is continuous. Finally, and above all, it favors immobilization of the joint, which is impossible during massage, and without which it is almost impossible to get cicatrization of the torn structures and complete recovery in sprains of any intensity. The bandage should be applied to the skin itself, care being taken to fill up the flat and depressed places with wadding, so as to give a uniform surface around the joint for the bandage to act upon.—*Revue de Thérap.*, July 15, 1884.

Total Retention of the Placenta—The retention of a part or the whole of the placenta is a cause of grave trouble, both by causing hemorrhage and by the absorption of decomposing materials. One must not, however, regard a woman as necessarily lost if the placenta be entirely retained. J. Favé reports a case to which he was called, seven hours after labor had terminated, in order to deliver the placenta. He found the uterus displaced, and every attempt to reach the placenta failed: on account of the feebleness of the woman he did not resort to instruments. Coffee and quinine were given for four days. The woman recovered, and became pregnant six months afterwards. Favé thinks it probable that the placenta shrivelled and came away at a menstrual period.—*Journ. de méd. de Paris*, July 19, 1884.

Spontaneous Rupture of the Bladder. — This case came under the observation of Dr. Lugeol, of Bordeaux, who reported it to the Société de Médecine of Bordeaux, in October, 1883.

The patient was thirty years old, and had a stricture dating about twelve years. Difficulty in micturition had existed for a long time, and, finally, he had complete retention. He made powerful efforts to urinate,

when he suddenly felt a violent pain in the left flank, which was accompanied by a chill. A few days afterwards, symptoms of a deep phlegmon manifested themselves. Lugeol made two deep incisions, one in the abdominal wall, and the other in the inguinal fold. These incisions gave exit to an enormous quantity of fetid pus and shreds of sphacelated tissue, which had a gangrenous and urinous odor. Three days later, he made a counter-opening on the other side of the abdomen, and put in a drainage-tube. Examination of the liquid which had flowed out of the first opening showed that it was urine. The patient passed urine through the urethra and the opening at the same time. There was, then, in this case, rupture of the bladder, extravasation of urine into the abdominal cavity, formation of a phlegmon, and a subsequent fistule. Lugeol then proceeded to make progressive dilatation, and, finally, to put in a sound, and leave it for several hours each day. The patient was cured.—*Journal de Méd. de Paris*, July 19, 1884.

PERSPIRATION OF THE FEET. — Perspiration of the feet is not a disease, but it is a great inconvenience, especially if accompanied by a disagreeable odor. Certain physicians think that there is no danger at all in suppressing this perspiration, and prescribe astringent lotions of oak bark, tannin, and other substances. Others hold that the infirmity should be protected, and prescribe only a non-toxic substance which will neutralize the odor. For this purpose, the following prescription is the best, and is very cheap:

℞.—Permanganate of potash, . 1 part.
Distilled water, . . . 100 parts.
Thymol, . . gtts. xxx (to ℥iij of water).

Filter-paper, linen, calico, or cork or straw soles may be soaked in this mixture, and then dried. They are then cut of the desired size, and a pair placed in the shoes every day. The feet are not colored by the potash. If there is any color, a thin coating of the white of egg, collodion, or tincture of benzoin may be used on the false soles.—*Bull. Gén. de Thérap.*, July 15, 1884.

TREATMENT OF CYSTITIS.—DR. WILLIAM GARDNER, Professor of Gynecology in McGill University, Montreal, in a lecture on cystitis (*Canada Medical and Surgical Journal*, June, 1884), spoke of the value of injections of nitrate of silver, as follows:

You will find, by most writers, solutions of one to two grains to the ounce recommended. This is far less valuable than a much stronger solution, thirty or forty grains to the ounce, of which I have had some recent very satisfactory experience. Such a solution causes severe pain and vesical tenesmus for a few minutes, and it is well to be prepared with your hypodermic syringe when administering it, which usually must be at the patient's own home. Confinement to bed for a day after is advisable. I may here mention a case I recently saw. The symptoms were of several years' duration, and came on after confinement. During nearly a year I had tried a variety of astringents, with only slight benefit, but my attention was directed, during the winter, to the stronger solutions of silver nitrate by an article in the PHILADELPHIA MEDICAL NEWS. I resolved to try the remedy. The results were most satisfactory. After two applications, the patient expressed herself as being better than for eight years. In this strength, the remedy ought not to be used oftener than once a week. Morphia has been injected to relieve severe pain. Solutions of one to two grains to the ounce may be employed.

DIAGNOSIS OF PERONEO-TIBIAL SPRAIN.—A case recently occurred in the service of M. Labbe, at the Beaujon Hospital, which well illustrated the difficulties sometimes encountered in the diagnosis between sprain at the ankle-joint and fracture of the fibula. There are four traumatic lesions which are usually found in this locality; 1. Tibio-tarsal sprain, properly so called, and, perhaps, the most rare; 2. Medio-tarsal sprain—these two varieties are easily distinguished from each other; but great difficulty is sometimes encountered in differentially diagnosticating 3—Peroneo-tibial sprain, or distention of the ligament which unites the tibia with the fibula—from 4. Fracture, with tearing of the external malleolus. In order not to fall into an error which would be decidedly disadvantageous to the patient, it should be noticed that in peroneo-tibial sprain the ecchymosis is seen a little in front of the anterior border of the fibula, while in separation of the external malleolus it is behind the bone, in the depression which separates it from the tendo Achillis. With regard to the pain, in the case of fracture it is seated immediately over the bone itself; but in the case of the sprain, the greatest pain is found in front of the anterior border of the bone. It is in these cases that the elastic bandage has such excellent effects.—*Revue de Thérap.*, July 15, 1884.

THUYA OCCIDENTALIS IN CANCER OF THE UTERUS.—The tincture of thuya occidentalis has been praised at different times as an efficacious remedy for rebellious condylomata, venereal growths, etc. It has also given excellent results in cases of simple chancre.

Four years ago, J. CHERON, who had used the drug for a long time, was particularly struck by an inaugural *Thèse* by M. J. Menier. The treatment of vegetations by the internal administration of thuya occidentalis had given results which in his hands were absolutely conclusive. Cheron repeated Menier's experiments, and though he did not get such remarkable results, the curative action of the tincture in vegetations was equally well demonstrated. He found that vegetations covered with epidermis, especially those which have a semi-corneal consistence, are not affected by the internal administration of thuya, so far as their disappearance is concerned; though they do diminish in size and consistence. Vegetations developed on mucous membranes, however, disappear completely when thuya is given internally; this has been abundantly shown in a great number of cases. In a word, the epithelial hyperplasias of the vegetations yield to the internal employment of thuya, while the epidermic hyperplasias do not. As regards the use of thuya in epithelioma of the cervix, Cheron's experience with it, which has extended over several years, leads him to say that in a certain number of cases he uses the tincture internally only; in a second class he uses it externally only; and in the third class he uses it both externally and internally.—*Revue de Thérap.*, July 15, 1884.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, AUGUST 16, 1884.

THE interest felt in the sessions of the International Medical Congress has widely extended since the famous gathering in London in 1881, and the proceedings of the eighth meeting now being held in Copenhagen are as eagerly looked for by the profession in this country as by their European *confrères* in whose midst it is convened. It therefore affords us great satisfaction to be able to lay before our readers a full summary of the proceedings up to Thursday, received by special cable dispatch from our own correspondent.

The meeting gives every promise of being successful, both as regards the number and eminence of the members in attendance and the character of the scientific work done, and we note with pleasure the presence of a goodly representation from the United States.

Next week we hope to be able to inform our readers that the Congress has accepted the invitation, that was presented on behalf of the American Medical Association by a special committee, which was appointed at the Washington meeting in May last, to hold its next session in this country in 1887.

THE SURGERY OF PULMONARY CAVITIES.

EXPERIENCE in the treatment of pulmonary pus-secreting cavities is very limited; but the past decade has shown, first, that in certain cases incision or paracentesis with drainage is unjustifiable; secondly, that in other cases one of these operations is imperatively demanded; and, thirdly, that there exist other cases in which the question of operative interference is not easy to decide.

The first group includes bronchiectatic cavities formed during the progress of pulmonary phthisis. The reported examples in which aspiration and the injection of medicated solutions, and incision with drainage have been resorted to, demonstrate that at the most nothing more than a palliative effect can be expected. In the majority of such cases the time has passed for doing any permanent good, and there is nothing in the operation to stay the resistless march of the disease, or prevent its extension to the adjacent lung-tissue.

In illustration of the truth of these statements, we may refer to papers read before the Congress of German Naturalists and Physicians, in 1873, by Mosler, of Greifswald, and before the American Medical Association, in 1880, by Pepper, of this city. In none of the cases was paracentesis with the injection of medicated fluids followed by positive results, nor was incision with free drainage more successful in the hands of Mosler. Thus, in one case in which the cavity was opened by an incision through the wall of the chest, the disease was found, on death a short time afterwards, to have spread to the neighboring lung-tissue, and to have produced general tuberculosis. In a second case, an external incision was made down to the pleura; the anterior wall of the cavity was carefully opened with a pair of forceps, the contents evacuated, and a canula inserted, through which various solutions were introduced, until the wound closed. Before the lapse of eight months, however, the patient was readmitted with all the signs of general tuberculosis, of which he died in six months.

The second group, or that in which interference is imperatively demanded, comprises suppurating echinococcus cysts, gangrene of the lung, and abscesses from ordinary causes. In a paper read before the Second Congress for Internal Medicine, at Wiesbaden, in 1883, Mosler exhibited a man, in whom, after a portion of the seventh rib had been resected, the sac was opened with the cautery, the parasites evacuated, and a drainage-tube inserted, through which antiseptic injections were made until the wound closed. He also referred to thirteen cases of a similar nature under his care, in which the great value of incision was apparent, and which will form the subject of a separate monograph. Fenger and Hollister, of Chicago, also had a recovery after incision of the lung and the extraction of an echinococcus cyst, which had caused an ichorous abscess. The report of the case may be found in the *American Journal of the Medical Sciences*, for October, 1881.

The first operation for gangrene of the lung was done by Lawson, of London, in 1879. Although the

symptoms were ameliorated, the patient died of exhaustion on the fourth day. The second operation was performed in the same year, by S. C. Smith, of Halifax, and the subject lived for ten days.

The third operation was done by Vogt on a patient of Mosler, in 1882. The case was that of a boy of fourteen suffering from septic fever and expectorating large quantities of pus mixed with shreds of dead lung-tissue, which proceeded from a cavity in the upper left lobe. One inch and two-fifths of the third rib having been excised, the lung was opened with Paquelin's cautery, and the gangrenous portions of the walls of the cavity were cauterized as thoroughly as possible, and the cavity well washed out with a solution of salicylic acid. A pair of long forceps was then passed downwards and backwards until the point was felt about an inch and a half below the angle of the scapula, when an incision was made over it, and four-fifths of an inch of the eighth and ninth ribs removed. The forceps was now used as a guide for the cautery, and a large cavity was entered, from which about ten ounces of very fetid fluid with numerous shreds of necrosed lung-tissue ran out in a stream. The walls of the cavity having in their turn been cauterized, an elastic drainage-tube was inserted, and the cavities thoroughly disinfected. At the expiration of a week the patient was dead, apparently from the effects of thymol and boracic acid, the application of which was followed by inflammation of the bronchial tubes, trachea, and larynx.

The fourth case of operation for gangrene is thus recorded by Mosler: "Under similar circumstances, Ed. Bull, of Christiania, attained a favorable termination. In a girl aged twenty-three, who suffered from putrid bronchitis, he succeeded in healing a gangrenous cavity by the operative treatment. In his case the cavity was likewise situated in the left lung."

The fifth case has recently been reported by Dr. Cayley to the Royal Medical and Chirurgical Society, and is recorded in the *British Medical Journal* for May 31, 1884. The patient was a girl of twelve who had gangrene of the base of the left lung, with pyæmic abscess secondary to suppuration of the mastoid cells. Mr. Gould punctured the lung with a large sized trocar and inserted a drainage-tube, through which fetid pus and a shred of necrosed lung were discharged. The child left the hospital cured eleven days subsequently.

The sixth and last case of which we have any knowledge has just been recorded by Fenger, in the *Journal of the American Medical Association* for July 19, 1884. A cavity in the right inframammary region having been detected by an exploring needle, an inch and a half of the fifth rib was excised, and the lung penetrated with the thermocautery. The cavity was washed out with an antiseptic solution, and a drainage-tube inserted. The hemorrhage was trifling. The symptoms gradually improved; shreds of gangrenous tissue were discharged during convalescence; and the patient was out of his bed at the end of the fifth week.

In this group are also included abscesses resulting from the entrance of foreign bodies into the bronchial tubes. In the discussion which followed the reading of a paper before the Royal Medical and Chirurgical Society, by Mr. Biss, also published in the *British Medical Journal*, of May 31st, Mr. Fowler, narrated a case in which Mr. Marshall opened and drained the lung between the eighth and ninth ribs for an abscess formed around a molar-tooth which had slipped from the dentist's grasp into the lung. The tube was worn for five months, and at the expiration of a year there still remained mucopurulent expectoration, and other signs of a small cavity.

The third group comprises those cases in which the decision of the question of operation is attended with much difficulty. Thus in the case of Mr. Biss, Mr. Marshall incised the soft parts over the tenth intercostal space, passed a trocar to the depth of four inches, and inserted a drainage-tube through which puriform fluid escaped. In ten days, signs of a cerebral abscess appeared, and in another ten days the man died. The necropsy revealed a number of bronchiectatic cavities in the lung, the largest of which had been pierced and drained, along with two abscesses of the brain.

Two cases of a similar nature are recorded by E. Bull in the *Nord. Med. Arkiv.*, Bd. xiv. No. 26, and Bd. xv. No. 17. In the first, an incision carried along the upper border of the second rib opened a superficial cavern in the upper lobe of the left lung, into which a drainage-tube was passed. At death, on the seventh day, a cavern as large as a goose egg was found in the lung, which was the seat of cheesy pneumonia, along with seropurulent pleuritis and pneumothorax. In the second case a large bronchiectatic abscess was opened, partly with the knife and partly with the thermocautery, in the right ninth intercostal space. On death from exhaustion in four weeks, in addition to the large cavity, the lobes were found to be the seat of numerous bronchiectases.

A fourth case has recently been recorded by Lauenstein in the *Centralblatt für Chirurgie*, No. 18, 1884. One inch and a half of the second rib having been resected, a trocar was passed into a cavity in the apex of the right lung, the passage enlarged with a pair of forceps, and a drainage-tube inserted. The patient was discharged in forty-five days, and was perfectly well one year subsequently.

In bronchiectatic cavities the result of pneumonia, the great obstacle to operative interference is the difficulty in making the diagnosis between a single large

cavity and multiple small cavities. Indeed, with all of the physical signs present, it may not be possible to reach the cavern, as happened to Mr. Godlee in three instances. If, however, the disease be limited to a single abscess, as happened in the first case of Bull, and in that of Lauenstein, it would certainly be right to open and drain it. For this purpose, after a preliminary incision down to the pleura, a large trocar and canula would be preferable to the knife, on account of the diminished risk of hemorrhage.

A review of the facts here presented offers not a little encouragement for the future of lung surgery. The wholesome maxim, "ubi pus, ibi evacua," is just as applicable to the lung, as it is to the brain, liver, spleen, or other organ; and we hold that the surgeon is open to the suspicion of timidity who fails to do his duty with suppurating pulmonary cavities, provided they result from other causes than tuberculosis.

DILATATION OF THE STOMACH.

At a recent meeting of the Société Medicale des Hôpitaux, M. Bouchard read a communication on the frequent occurrence of dilatation of the stomach and of the consequences of this morbid condition. He has observed two hundred and twenty cases of gastric dilatation, and his statistical researches have proved that thirty per cent. of sickly people are the subjects of this affection. Amongst patients treated for chronic maladies dilatation is found as frequently as sixty per cent. More often this distention is not revealed by any symptom except such as is revealed by physical examination of the organ in question. There are no digestive troubles in about a third of the number of cases. In the majority of cases the sign of dilatation is a "bruit de clapotement," a splashing sound when the gastric region is percussed below the level of a line which joins the navel to the lower border of the last left rib. To have any clinical significance, this sign must be observed in the morning when fasting or when the patient has had only a glass of water.

According to M. Bouchard, dilatation is the cause and not the consequence of dyspepsia. Gastric dilatation may lead to numerous troubles, of which the following are the principal: 1. Digestive disturbances, distention, eructations, acidity, fetid breath, constipation, mucous discharges, hemorrhoids. 2. Congestion and swelling of the liver, producing depression of the right kidney, which has been regarded by Bartels as primary. 3. Nervous disorders, consisting in headache, nightmare, migraine, vertigo, weakness of memory, loss of strength, priapism, hallucinations, palpitations, shortness of breath, post-sternal pain, angina pectoris, etc. 4. Alterations in the urine, which may contain urate sediments, sugar, albumen, and peptones. 5. Cutaneous eruptions. 6. Bronchitis, coryza, asthmatic attacks. 7. Cardiac lesions, purpura, and nodular rheumatism.

All these manifestations do not exist at once, but their existence, isolated or simultaneous, has allowed of a division of the malady into various forms: dyspeptic, enteric, hepatic, renal, cardiac, cutaneous, rheumatic, consumptive. The links which bind gastric dilatation to these various conditions are more difficult of demonstration

Dilatation of the stomach first hinders the elaboration of the food, thereby provoking unhealthy fermentations and multiplication of the figured elements in the stomach. Products of fermentation of the alimentary bodies are noxious and even, at times, toxic. It is the injurious action of these products on the economy which are the worst pathological consequences of dilatation of the stomach. M. Dujardin-Beaumetz, in discussing this paper, urged wisely that the splashing sound heard on percussion is, perhaps, hardly sufficient to diagnosticate dilatation.

THE PATHOGENIC MICROBES OF GONORRHŒA.

The microbe of gonorrhœa was discovered in 1879 by Neisser, and was given the name of gonococcus—the seed of numerous production—and in a recent number of the *Nordiskt Medicinskt Arkiv*, Dr. Edward Welander has an elaborate article, in which he concludes that they are characteristic of the disease.

The gonococcus is always found in groups, never in chaplets; it is seen in the interior as well as at the exterior of pus-cells, frequently in large groups upon the epithelium, and besides in a free state in the secretion. The proofs that they are the pathogenic microbes of blenorrhagia are, according to Welander, that he has found them in 129 cases of acute, and in 15 cases of chronic blennorrhagia in the male, and in the purulent urethral secretion of 49 females, while he has not found them in other secretions; in 25 cases of blennorrhagia in all of which the gonococcus was found, he ascertained the persons who communicated the disease, and in them too the gonococcus was present. Further, inoculation with secretions which did not contain the gonococcus gave negative results, while blennorrhagia followed those cases in which purulent matter containing the gonococcus was used. Still, the scientific proof is wanting, for the few culture-experiments that have been made are incomplete, or discredited; and so far the cultivation of the gonococcus has proved exceedingly difficult.

In the treatment various antimicrobic remedies have been tried, such as carbolic acid, corrosive sublimate, and iodoform, but the results have not been satisfactory. Welander regards an abortive treatment during the first two or three days as quite proper, and his method is first to cleanse thoroughly

the anterior portion of the urethra, chiefly the navicular fossa, with cotton and forceps, thus removing a quantity of epithelial cells with the gonococcus in or upon them, and then cauterize with a solution of nitrate of silver.

So far, it seems that the discovery of the gonococcus has not helped the treatment of blennorrhagia; but it certainly is a great gain to be able to say positively when the contagiousness of the disease has ceased, and when, for example, a man may enter married life safe from the danger of communicating disease to his wife, and thus making her suffer for his sins, giving her not only different forms of intrapelvic inflammation, but, according to Dr. Noeggerath's views, making her sterile. In medico-legal cases the discovery may prove of the greatest importance. Thus in cases of leucorrhœa in children, against whom it has been charged that rape had been attempted, and disease thereby communicated, the absence of the gonococcus in the vulval or vaginal discharge would at once disprove the charge.

As an incidental practical point, Welander suggests that the oculist may be enabled, by determining the presence or the absence of the gonococcus, to ascertain the nature of a purulent inflammation of the conjunctiva.

TREPHINING IN TRAUMATIC EPILEPSY.

FROM a paper read before the American Surgical Association at its recent meeting, and published in *The American Practitioner* for July, by DR. W. T. BRIGGS, of Nashville, we learn that that accomplished surgeon has obtained the most brilliant results from trephining for epilepsy arising from injuries of the head. Of his 30 cases, 25 were cured, 3 relieved, 1 was not benefited, and 1 died. The wounds were dressed after the open method for free drainage, and germicidal agents were not employed.

That these excellent results, as well as the low rate of mortality, are not, however, always attainable, is shown by an examination of a larger number of cases derived from the practice of many operators. Thus, Walsham has tabulated in *St. Bartholomew's Hospital Reports*, vol. xix., 130 examples of trephining for traumatic epilepsy, of which 75 were completely cured, 18 were improved, 7 were not benefited, and 30 died. It should be mentioned that one of Briggs's cases appears in the tables, but if we substitute for it a recent recovery by Warren, of Columbus, Ohio, we arrive at the following results: 160 cases have yielded 100 cures, 21 improvements, 7 failures, and 31 deaths.

It is doubtful whether the same ratio of complete recoveries, namely, 62.5 per cent., has ever been attained by internal medication; and as the death-rate—19.37 per cent.—is not excessive, it would appear that the procedure is eminently proper, especially if it be resorted to as early as possible after the fits have declared themselves.

SELF-INFECTION IN CHILDBED.

IT has been for some time generally held that so-called puerperal fever is either autogenetic or heterogenetic. But, if the disease depend upon a specific microbe, this classification can no longer be admitted; and, indeed, to suppose that the lying-in woman can create within herself a puerperal poison which, in its evolution, manifests the same symptoms as are shown when the infection obviously has an external source, and which communicates a like disease to other women, seems illogical.

Ahlfield, among others, has upheld recently the doctrine of self-infection, adducing cases of puerperal disease in which, as he believed, the patients were effectually guarded against all external infection. But DR. LEOPOLD LANDAU criticises, in a recent number of the *Archiv für Gynäkologie*, Ahlfeld's views, and shows that he is in error as to there being perfect protection in the cases referred to, from germs coming from the outside, and that these germs may reach the genital organs in spite of his antiseptic precautions. Landau believes that, in a therapeutic point, it is of the greatest importance that all hypotheses such as that of self-infection should be rejected, for injury will thereby be prevented.

OGSTON'S OPERATION FOR GENU VALGUM.

SUBCUTANEOUS division of the internal condyle of the femur for knockknee, has, according to the report made to the recent Surgical Congress at Berlin, by PARTSCH, been done thirty-four times at the Breslau Clinic, from 1878 to 1884. All recovered, despite the fact that the saw broke in one, and the fragment could not be extracted. Of the four patients in whom the record could be followed for at least three years, two were completely well without any deformity, while a light grade of genu valgum persisted in the others.

Partsch's views as to the superiority of this operation over Macewen's, met with warm opposition in the discussion which the reading of his paper elicited. Volkmann thought that it ought to be discarded, not only on account of the deaths which have occurred, but from the fact that the condyle occasionally fails to unite, that it is liable to give rise to deformity of the joint, and that opening of the joint is unnecessary when the curvature is seated between the shaft and epiphysis. In one of Lange's cases, there was so much interference with the subsequent growth, that the knee-joint was practically useless; while of five patients under the care of Mikulicz, two recovered with anchylosis.

SOCIETY PROCEEDINGS.

INTERNATIONAL MEDICAL CONGRESS.

Eighth Annual Session.

Held at Copenhagen, August 10th–16th, 1884.

Special Cable Dispatch from Our Own Correspondent.

COPENHAGEN, AUGUST 14TH. Pleasant weather has favored the gathering of the Eighth Session of the International Medical Congress, which was

FORMALLY OPENED

in this City on August 10th with imposing ceremonies. The event was graced by the presence of Their Majesties, the King and Queen of Denmark, and the King and Queen of Greece, and of the Danish Council of State, foreign ministers, and other State officials, who, decorated with numerous badges and orders, added to the brilliancy of the occasion.

The membership of the Congress is large, and the different countries are well represented. Upwards of

SEVENTEEN HUNDRED MEMBERS ARE REGISTERED,

including about three hundred and fifty delegates from Denmark, one hundred from Sweden, one hundred from Norway, and about eleven hundred and fifty from various other countries.

PROFESSOR P. L. PANUM, CHAIRMAN of the Organizing Committee, delivered the following

INAUGURAL ADDRESS,

Sire, Your Royal Highnesses, Ladies, and Gentlemen: Having the honor assigned me to open the Eighth International Congress of the Medical Sciences, my first duty is to thank His Majesty, the King, in the name of my colleagues, for the favor which he has bestowed upon us by deigning to be the Patron of our Congress.

I have, at the same time, the honor of thanking all the royal family for giving us the honor of its presence at this inaugural meeting.

This patronage and this presence are for us the best auspices of a happy international reunion. May the Chief of this august family, which has reunited in harmony, by the most intimate and gracious ties, the different nationalities of Europe, be for us the symbol of the international principle which should characterize our science and our assembly! Let us hope that the members of our Congress will be united by sentiments as fraternal, and be elevated above the boundaries of special nationalities, as are the illustrious members of the Royal Family of Denmark! But that should not be difficult for us who are united in an aim so international as medical science. Is it not our object to combat the enemies of the whole human race; the diseases of man and the causes of those diseases? This noble aim should inspire us all with fraternal sentiments. I have still the duty of thanking, in the name of all my colleagues, the Ministers, the Representatives of the Chambers, the Magistrates, the representatives of our City, and all those of our citizens who have favored and protected our Congress, and given friendly assistance at this inaugural meeting.

To you, dear and learned colleagues of foreign countries; to you who have braved the fatigues and annoyances of a long voyage to assist and participate in this Congress, even despite the universal alarm caused by the cholera, to you I extend a cordial welcome, not only in the name of my colleagues, but also in the name of all my fellow-citizens.

I should, however, say that we have only accepted this honor with timidity, and not without hesitation. The brilliant and incomparable success of the Congress in London, the great efforts there made, the enormous resources of the greatest and richest city of the world, still further increased by those of the vast British empire—all this might well intimidate us.

I do not yet understand the motives of the resolution passed at the last Congress, in London, desiring that the next Congress be held in one of the capitals of the Scandinavian countries, either at Stockholm, Copenhagen, or Christiania; but I well know that my Danish, Swedish, and Norwegian colleagues have been highly sensible of the honor which the Committee of the London Congress did them in designating one of these cities as the place for holding the Congress.

Modesty would have prevented the Danes from disputing the preference for Stockholm, the capital of a larger country than ours, and whose situation is more picturesque than that of Copenhagen; but Stockholm could not accept this honor on account of temporary circumstances; and Christiania, fearing that her resources were insufficient, did not accept it.

The hesitations with which we were inspired by a sense of modesty, though well justified, disappeared, however, when the Committee of the London Congress expressed the formal desire that Copenhagen should be the place of meeting of the Eighth International Congress of the Medical Sciences. I suppose that preference was given to our city chiefly on account of its more central situation, and greater convenience of access for strangers of other countries than that of Stockholm and Christiania. The proposition of the London Committee was promptly accepted and cordially embraced by the physicians of Copenhagen, and everything which we thought possible has been done to assure the success of the Congress. But we know only too well that we have a thousand reasons for appealing to your indulgence.

It is then to the London Committee that we owe the

honor of the selection of Copenhagen as the place of meeting for this Congress. I am happy to be able, in the name of my Danish colleagues, to address our personal thanks to the illustrious President of the London Committee, Sir James Paget, and to the eminent Secretary-General of that Committee, Sir William MacCormac, and to be able, in the name of all the members of our Congress, to express our great pleasure at seeing them here.

It would have been, however, without doubt imprudent for the Danish physicians to have accepted the Congress could we not have counted on the assistance of our colleagues of the other Scandinavian countries. But we were well assured of your assistance, dear colleagues of Sweden, Norway, and Finland. United to us by a common language which presents only very slight differences of dialect, we have already and for a long time worked together in the Congress of Scandinavian Physicians and Naturalists, and been collaborators in the same journals. In the name of the Danish physicians I thank you, dear colleagues from sister countries, you who have desired to give us your assistance in the work of organizing the different Sections, and you also who have come as members of the Congress. You are not strangers here, you are at home, and I am convinced that the visitors from other countries regard you as of us, because they fixed the place of meeting of the Congress with you as well as with us.

You also, dear and learned colleagues of other countries and languages, and of different nationalities, from Germany and from Austria as well as from France and Belgium, from England and North America, from Russia and Switzerland, from Holland and Italy, and from all the other countries of the two hemispheres, you are all equally welcome, from the East as from the West, from the South as from the North. You all come as allies, as combatants against our common enemies, which recognize no nationality, and you come bringing to the arsenal of science new arms which equally belong to all nations, and which will always remain the property of the whole human race.

Nationality counts for nothing in our science, and has nothing to do with our Congress. We are not here to discuss either national or political problems. On the contrary, any discussion of these subjects on this occasion would be entirely out of place. Every manifestation of national pride or of predilection for any particular nationality would be here offensive to others who equally have the right to be proud of their nation, and whose duty it is to love their country. It goes without saying that all of us will ever preserve these patriotic sentiments deep in our hearts.

It is necessary, however, to use a language belonging to one or the other of these nationalities, for the ancient language, the Latin, is to-day no longer practicable in our science. I would be happy, gentlemen, to be able to address you in all your languages at the same time; but, that not being possible, I admit that I have been much embarrassed to make a choice.

As a Dane, it would be more convenient for me to use the Danish language, but this language would not be understood by most of our visitors. It would be very easy for me to use the German language, in which I have taught my science for a number of years. But I think that on this occasion I should prefer the French language, because it would most probably be best understood by every one, because it is recognized in our country as the language of polite society, and finally because it has been chosen for the official language at most of the preceding Congresses.

At our Congress it is not necessary to use languages as flags of our nationality, but as signals by the aid of which men of different nations approach to exchange the treasures of science, and to ask or offer good-will.

As a symbol of a nationality, language should certainly be pure, and not tainted with errors of grammar or foreign pronunciation, but, as a means of clear understanding, grammar and pronunciation have only a real value in so far as they are necessary to express thought. It is of little importance to a ship whether the sails be white, red, black, or spotted, so long as they serve to drive forward the vessel.

You who have the happy privilege of using as your native language French, English, or German, you will without doubt have the goodness to excuse us for offences against the grammar of your idioms, and I hope that you yourselves will on some similar occasion have the modest privilege which we now claim for ourselves, of being willing to speak, in your tour, some foreign language, rendered necessary by these circumstances. But in any case, in speaking your mother-tongue, I hope, out of regard for others, you will have the kindness to speak slowly and distinctly; otherwise, those who use their own language will, perhaps, be less readily understood by those who speak a foreign language, whether well or badly.

I have made these remarks because I am convinced that the success of this Congress and of succeeding International Congresses will always depend on the harmony and organized coöperation of men of science from every country, of all nations and languages. Whatever reason different nations may have for warfare, they should ever be united as brothers in all that concerns the advancement of science, and combat the brute forces which are hostile to humanity, as well as the enemies of our science, who are fond of comparing it to the building of the Tower of Babel.

Gentlemen, the fabulous Tower of Babel was evidently something very different from our science, for it is, as you well know, of celestial origin. It has produced some immortal works, and is of use to all the world. It demands devoted and modest workers, while the frivolous ambition, the pride, the vanity, the egotism, the rivalry, of men and nations, have never pro-

duced anything but some Tower of Babel, soon destroyed by the same forces. Let us hope that the results of our Congress will be worthy of this reunion of the most distinguished physicians of our time, who in good will have come here to communicate to us the treasures of their observations and of their researches!

At the conclusion of Professor Panum's speech, brief

ADDRESSES IN RESPONSE

were made by Sir James Paget, of London; Professor Virchow, of Berlin; and Dr. Pasteur, of Paris.

The Congress then proceeded to effect a permanent organization, and elected the following

OFFICERS:

President.—Prof. P. L. Panum, of Copenhagen;

Secretary-General.—Prof. C. Lange, of Copenhagen; and the following

HONORARY PRESIDENTS:

Sir James Paget, Sir William Gull, and Sir William MacCormac, of London; Prof. Henry W. Acland, of Oxford; Sir Risdon Bennett, Sir Joseph Lister, Sir Spencer Wells, and Mr. John Eric Erichsen, of London; Dr. Eben Watson, of Glasgow; Prof. John Marshall, of London; Dr. John S. Billings, of Washington, D. C.; Prof. Austin Flint, of New York; Dr. Louis Pasteur and Prof. A. Verneuil, of Paris; Prof. Chauveau and Prof. Ollier, of Lyons; Prof. Jaccoud, Prof. Hardy, Prof. Ranvier, Prof. Cornil, and Prof. Trélat, of Paris; Prof. Lépine, of Lyons; Prof. Virchow, of Berlin; Prof. von Kölliker, of Würtzburg; Prof. Frerichs, of Berlin; Prof. Volkmann, of Halle; Prof. Esmarch, of Kiel; Prof. His, of Leipzig; Prof. Hensen and Prof. Flemming, of Kiel; Prof. Hirsch; Prof. Munk and Dr. Liebreich, of Berlin; Prof. von Liebermeister, of Tubingen; Prof. Tilanus, of Amsterdam; Prof. Rosenstein, of Leyden; Prof. Engelmann, of Utrecht; Dr. Reyher and Dr. Rauchfuss, of St. Petersburg; Prof. Tommasi-Crudeli, of Rome; Prof. Bottini, of Pavia; Dr. Crocq, of Brussels; Dr. Lombard, and Prof. Prevost, of Geneva; Dr. von Meyer, of Zürich; and Prof. Kolomnin, of St. Petersburg.

On the evening of the opening day, the President, Prof. Panum, entertained at dinner two hundred of the foreign members of the Congress. After the removal of the cloth, numerous toasts were proposed, in response to which speeches were made by Prof. Panum, Sir James Paget, Prof. Virchow, Dr. Pasteur, and others.

On the following day the fourteen Sections of the Congress were formally opened. They were largely attended, and a number of valuable papers were read.

In the afternoon the Congress met in general session, when Dr. Louis Pasteur delivered an address on

HYDROPHOBIA,

in which he fully discussed the subject of inoculation, and related his latest experiments on this subject.

At the conclusion of his address he was greeted with enthusiastic applause.

In the evening, the President of each Section entertained the members of his Section at dinner, thus enabling those interested in each specialty to meet one another socially, and constituting a very pleasant feature of the Congress.

On Tuesday, at the general meeting, Prof. Tommasi-Crudeli, of Rome, gave an address on

THE NATURAL PRODUCTION OF MALARIA, AND THE MEANS FOR MAKING MALARIAL COUNTRIES MORE HEALTHY.

Prof. A. Verneuil, of Paris, then delivered an address on

THE NEOPLASTIC DIATHESIS.

Dr. John S. Billings, U. S. A., on behalf of the Committee appointed by the American Medical Association, in a brief speech, then delivered to the Congress a formal

INVITATION TO HOLD ITS NEXT SESSION IN WASHINGTON.

The invitation was favorably received, and will probably be accepted. No other invitations were presented, but the cities of St. Petersburg and Berlin were suggested as eligible places for holding the meeting. The decision of the Congress was deferred until the final meeting on Saturday.

Wednesday was given up to an

EXCURSION TO ELSINORE,

an old and interesting seaport of Denmark, where is laid the scene of Shakespeare's "Hamlet," and to the beautiful Castle of Kronborg, overlooking the Sound. The members, with their ladies, embarked on three steamboats, and greatly enjoyed the sail, of about twenty-four miles, through the Sound. The excursion occupied the whole day, and constituted a very agreeable feature of the meeting.

Each morning upon the adjournment of the Sections the members of the Congress are entertained at luncheon.

A COMMITTEE OF DANISH LADIES

are constant in their attentions to the ladies accompanying the members of the Congress, and private hospitality is unbounded. Numerous excursions, by land and water, are upon the programme.

The meeting is universally pronounced a brilliant success, and the members are highly gratified at the cordial and hospitable manner in which they are received and entertained.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, August 4, 1884.

The President, D. A. K. Steele, M.D., in the Chair.

(Specially reported for The Medical News.)

Dr. J. H. Etheridge read a graphic historical account of

THE TREATMENT OF CHOLERA.

Phosphorus was extensively employed before this century. Sixty years ago calomel, opium, and vene-

section were the important therapeutic agents. James Johnson, in his classical work on *Tropical Diseases*, published in 1824, says, "Start the bile, then support the powers of life." In the epidemics of 1826–27, the new remedies were carbonic acid, hydrocyanic acid, nitro-muriatic acid, chloride of gold, chloride of sodium, oxygen, arnica, buchu, purgatives, boiling hot water, cold water, counter-irritants, actual cautery, and chlorine. The epidemic of 1832–34 was a terrible one, and the list of therapeutic agents is long. Acids of all kinds, alkalies, albumen, bandaging, hot-air and sand baths, vapor baths, belladonna, bile, tobacco, sulphate of copper, coffee, electricity, horseradish, transfusion, the injection into the bladder of medicated solutions, were employed in the treatment of the disease. An infusion of horseradish, calomel, and opium gained much reputation. Ice-water, intravenous injections of salines, iron, juniperberry oil, lead, lime-water, intravenous injections of milk, alcohol, turpentine, strychnia, the ligature of the extremities, croton oil, abdominal tourniquet, are also mentioned.

In 1848, anæsthetics, arsenic, camphor, capsicum, carbon disulphide, gum powder, hydrotherapy, *Perkins's tractors*, and ergot, were, in turn, remedial agents. In 1854, alcohol, chloride of calcium, eupatorium, garlic, potassium permanganate, quassia, sugar, *vaccination*, and *hard cider* were popular remedies. It was during this epidemic that B. W. Richardson, of London, advised the injection of water into the peritoneal cavity. About this time the nervous system began to receive attention from pathologists, and nervines were introduced. Nitrite of amyl, calabar bean, coca, spinal ice-bags, hypodermic injection of water, and the dosimetric system received the attention of the profession.

In 1873, sulphurous acid, antimony, chlor-alum, were added to the list.

DR. J. N. DANFORTH then discussed

THE PATHOLOGY OF CHOLERA.

He said that every organ of the body was more or less affected, but that pathologico-anatomical changes in the blood, intestinal walls, and kidneys were the three uniform lesions. The blood was thickened—sometimes to currant-jelly consistence—and contained microbes.

The intestinal villi were deprived of their epithelial covering, and Peyer's glands were enlarged. In the alvine discharges he had found, in 1873, epithelial cells, pus, blood, and microbes. Ziegler, Cornil and Ranvier, and Labarre (?) deny the existence of these epithelial cells in *ante-mortem* discharges. The arteries supplying the intestines were constricted, while the veins were greatly distended. The intestinal walls were, therefore, in a state of intense passive congestion. The kidneys presented the changes characteristic of acute fatty degeneration. The cortical glandular cells exhibited the fatty metamorphosis first. He agreed with Ziegler, Cornil and Ranvier, and Labarre (?) that the etiological relationship of Koch's microbe was not established. Dr. Danforth's remarks were well illustrated by drawings.

DR. W. T. BELFIELD was called upon for information in relation to

THE GERM-THEORY OF CHOLERA.

He said that Dr. Robert Koch had found in the intestinal walls of cholora patients in India and Egypt a microbe recognizable by its size, form, and reaction to staining fluids. This microbe had not been found in any other tissue or organ. The constant association of this microbe with cholera was established. Its causal relationship was not proved. Koch had failed to produce cholera in dogs, rabbits, cats, and white rats, by the inoculation of the cultivated bacillus. He had seen the microbes in a rapidly multiplying condition in the intestinal walls. Until human animals were placed at the experimenter's disposal, Dr. Belfield was of the opinion that positive evidence as to the *rôle* played by the cholera bacillus would be lacking. In anthrax the etiological relationship of the anthrax bacillus had been clearly proved. In no other affection had the inoculation of cultivated bacilli produced the respective disease.

As regards the natural history of Koch's cholera microbe, it flourishes in alkaline solutions of a low degree of saturation, while acid liquids are not tolerated. It must be remembered that choleraic discharges are usually alkaline.

DR. JOHN BARTLETT, a member of the committee of three appointed, in 1873, to investigate the pathology of cholera, made some interesting remarks with reference to the *rôle* of the cholera bacillus. In 1874 he was engaged in experiments with "Saulsbury's ague fungus." He had observed a fungus—a cell—in a developing fluid, aggregate about itself a crystalline body, tangible and in quantities—bearing the relationship to the fungus that coral bears to the coral insect. This crystalline body in time put forth buds, which were of a green color. Presently, from these green buds, a clear protoplasmic mass was developed, which gave origin to cells, each one of which resembled the cell observed in the first place. May there not be some stage in the development of the cholera microbe, when it is invisible, and at the same time functionally active?

DR. CHARLES GILMAN SMITH made an able speech on

THE PROPHYLAXIS OF CHOLERA.

He believed that the disease was highly contagious, and was accordingly surprised to hear a woman with the experience of Florence Nightingale, pronounce against the theory. The epidemic of 1854, which he had witnessed, furnished evidence sufficient to convince him that the disease was contagious, and that it was propagated by the decomposed dejecta of cholera patients. Without denying the possibility of its origin *de novo*, he knew of no recorded cases of such character. The disease, once developed, follows the lines of travel. This theory was sustained by the fact that cholera was unknown in Australia. A thorough quarantine of ships and railroads should be instituted. Of the effectiveness of a thorough quarantine he had no doubt. In the last epidemic there was a cholera focus at Butterfield and Thirtieth Streets in Chicago. The vigorous measures taken in removing the inhabitants and purifying the premises had stamped out the disease.

As bearing upon the question of prophylaxis, a letter from DR. JOHN H. RAUCH, Secretary of the State Board of Health, was read, of which the following extract is of interest:

The condition of the river, and especially of the South Fork, is a matter of the utmost importance to Chicago in the event of a cholera epidemic; and, indeed, at all

times. Sixty thousand cubic feet per minute transferred from the river to the canal will keep the former clean and harmless; will prevent the possibility of pollution of the water supply at the crib; will affect sixty-six per cent. of the South Fork, and will so dilute the sewage as to make the canal unobjectionable to the communities along its banks. To secure this transfer requires two things:

1. That the pumps at Bridgeport be operated to their full capacity.

2. That the waters of the Desplaines River be prevented access to the South Fork through the Ogden Ditch.

If the Society can achieve this, it will render a most important service to Chicago, will help De Wolf in his arduous work, and earn the gratitude of one hundred and fifty miles of cities, towns, and hamlets along the canal and Illinois River.

Dr. N. S. Davis gave his experience in the epidemics of 1849, 1850-52-54, 1868, and 1873, on the

SYMPTOMATOLOGY AND TREATMENT OF CHOLERA.

Dr. Davis witnessed the epidemic of 1849 in New York City, and the others in Chicago. He did not believe in the germ-theory of the disease. In addition to an epidemic influence—whatever that might mean—there were three conditions necessary to cholera, viz., a high temperature, a soil in at least in a damp condition, and the presence of decomposing organic matter. He was sceptical as to the efficacy of any quarantine.

There was but one affection with which cholera could be confounded—cholera morbus. The differential diagnosis was usually not a difficult matter. In cholera, except in the height of an epidemic, there is a premonitory, painless diarrhœa, lasting from a few hours to several days. Accompanying this diarrhœa is a feeling of lassitude, weakness, general *malaise*. In cholera morbus there is no premonitory diarrhœa, but vomiting and purging occur at once, with great intestinal pain. Following the premonitory diarrhœa, in cholera, the patient complains of dizziness, and prickling sensations over the skin surface, and particularly in the extremities. Soon the patient vomits the stomachic contents; then he discharges by the mouth and anus the characteristic rice-water evacuations of cholera. After the first up and down movement, paroxysms of vomiting and purging recur every ten or twenty minutes. The amount of this choleraic discharge is very variable, but may measure half a gallon at a time. If set aside in a glass vessel flocculi settle to the bottom of the vessel, and the turbid, supernatant fluid becomes clearer. This fluid is composed of the serous elements of the blood, epithelial scales, and bacteria. In a fatal case, the patient now literally withers; symptoms of intense, acute anæmia supervene; the skin surface is alternately bathed with cold perspiration and shrivelled up. The eyeballs shrink back into their sockets; the finger-nails are blue, the lips pallid; the tip of the nose is cold like a dog's; the breath is distinctly cool. Intensely painful cramps are felt and seen in all voluntary muscles. The muscles of the calves, thighs, and upper extremities are seized first. The tongue is colorless, and the voice husky. The urine is entirely suppressed at an early stage of the disease.

In the height of an epidemic, the disease may run its course with frightful rapidity. In the epidemic of 1854, he had under his care a strong, healthy Scandinavian who, without any premonitory diarrhœa, was seized with serous vomiting and purging, and died three or four hours after the onset of the attack.

In cholera morbus, there is not this *ensemble* of the symptoms of acute anæmia, and the glandular secretions are not suppressed.

As regards treatment, he had few suggestions to make. In the premonitory stage, put the patient to bed at once—*when he is taken*—and treat as cholera morbus with the usual remedies when the patient commences to discharge by mouth and anus. Wait until the patient has become so exhausted by vomiting and purging that he can retch no longer, then put on the back of his tongue a powder containing one grain of calomel, one-sixth grain of morphia, and four or five grains of white sugar. He impressed upon his hearers the importance of doing this quickly, and said it was folly to wait for stated periods to give medicines in such cases, for the chances were that a dose would be given first on the recurrence of the vomiting, and, therefore, no good would come. As an enema, he gave ten grains of acetate of lead and one-half grain of morphia, in two ounces of water, directly after a paroxysm of purging. Apply dry heat to the extremities; sinapisms alternately to belly and back. After reaction has occurred, give dilute solution of table salt and small quantities of coffee and milk.

The cramps were best treated by firm compression. Rubbing was of less value. When vomiting ceased, he had been in the habit of giving, since 1849, small doses of the following mixture:

R.—Carbolic acid,	gr. ¼.
Tr. gelsemii,	♏v.
Paregoric,	ʒ½.
Water,	to ʒj.—M.

The thanks of the Society were tendered the venerable head of Mercy Hospital, and it was resolved to continue the discussion of the treatment of cholera at the meeting two weeks hence.

CORRESPONDENCE.

ETHERIZATION BY THE RECTUM.

To the Editor of The Medical News.

Sir: It has amused more than it has surprised me to find etherization by the rectum spoken of in many medical journals as a novelty. Your correspondent, J. C. R., in the number of The News for August 2, refers to several European writers who have described this method, beginning with Pirogoff, in 1847; but he has overlooked the description of it which appeared in each of the four editions of Stillé's *Therapeutics*, from 1860 to 1874.

The language there used is the following: "The method of Pirogoff, which consists of injecting the vapor of ether, and ether itself largely diluted with water, into the bowel, has been condemned by some who have used it, on the ground of its occasioning ex-

treme flatulent distention of the abdomen. But many of those who have employed it to relieve painful internal maladies, such as neuralgia, spasm of the muscles of deglutition, lead colic, inflammatory pains of the joints, and cancer of the intestinal tube, report favorably of its anodyne and antispasmodic effects." The authority given for these statements is Canstatt's *Jahrbuch*, 1849, page 190. Æ.

THE USE OF THE OBSTETRICAL FORCEPS AS A SPECULUM.

To the Editor of THE MEDICAL NEWS.

SIR: The following extract from Blundell's *Principles and Practice of Obstetrics*, published in 1834, will be read with interest in connection with the valuable paper by Drs. Price and Faught in the last number of THE MEDICAL NEWS.

We wish only to suggest that in some cases the reduction of the fœtal head may be so great that the forceps will slip, so that while the instrument is useful in protecting the maternal parts from injury during perforation, after this has been done, it may be useless for the purpose of extraction:

"If the contraction of the pelvis be slight, and craniotomy be required, those who are in the habit of using long forceps will probably have first made trial of this powerful instrument before they have recourse to the destruction of the child; and, if it so happen that the long forceps is still applied to the head at a time when craniotomy is proposed, it will be better still to leave the instrument on the cranium, as its operation may afterwards facilitate both the operation itself and the subsequent abstraction of the fœtus."

Yours respectfully,
T. P.

PHILADELPHIA, August 2, 1884.

A CASE OF ALMOST COMPLETE ADIPOCERATOUS TRANSFORMATION.

To the Editor of THE MEDICAL NEWS.

SIR: In the latter part of April, I, with two local physicians, was requested to examine a recently exhumed body, supposed to be petrified.

On inspection, the coffin, with its enclosing box, was found to be well preserved. Opening these, we found the body of a large, portly woman, probably fifty years of age, whose death is said to have occurred in September, 1876, from diabetes mellitus. The exposed parts of the body were covered with a grayish mould, easily wiped away, disclosing the skin, which, in appearance, did not differ greatly from that of a recent corpse.

The features were perfect, with the exception of the eyes, which were deeply sunken, the ball being disorganized. Hands preserved, with the exception of slight decomposition around the roots of the nails. These were the only external evidences of decay.

No hair existed on the head at the time of death, but some short hairs on the lip were found to be firmly attached.

On attempting to remove the clothing, the cotton garments tore like wet paper; the silk dress was in a better state of preservation.

The entire body was well preserved, and in complexion similar to the face (no mould having formed under the clothing). On the breast were found suggestions of cadaveric lividity; also several ulcers, said to have existed for some time before death.

Immediate percussion over various parts of the body elicited a note not unlike that obtained by striking a plastered wall. Palpation over the soft parts gave an impression of cartilaginous resistance.

A portion of the abdominal wall was cut away (the resistance to the knife being about that of moderately dried soap), and was found of the thickness usual in fleshy persons, but converted into a mass of adipocere, as was also the fat which had loaded the omentum.

A portion of the intestines was outlined by a thin, friable membrane, and the liver was almost perfectly preserved, of a consistence somewhat firmer than normal, and of a *café-au-lait* color. Excepting this, no viscera were found, but the cavity contained a small quantity of fluid having an odor similar to that found in the abdomen of a pickled cadaver—as did the gas which escaped on making the first incision.

The thorax contained nothing but gas and a small quantity of *débris*, which appeared to be the remains of the heart. This cavity was opened by cutting through the sternum and ribs; no more resistance was offered to the knife by the bone than by any other tissue. In the section, the cancellous structure of the sternum and ribs, and structure of the cartilage could be demonstrated, but all were of the same waxy consistency.

At the request of the friends, the cranium was not opened, but a pin inserted in the frontal region appeared to pass through the external, but to be arrested by the internal table of the skull.

The place of first interment was on an island some miles down the river, hence was not visited, but was described as a small sandy knoll, surrounded by a marsh or swamp, which always contains water more or less charged with organic matter, while on the same island limestone is obtained. The coffin had the appearance of having been completely submerged, and when first seen was partially filled with a soapy-looking water.

NEWS ITEMS.

CINCINNATI.

(*From our Special Correspondent.*)

THE HEALTH OF THE CITY during the entire summer has been exceptionally good. With the exception of the month of June, the rate of mortality has been below the average. There have been no epidemic outbreaks, and the ailments usually accompanying the heated term have not been of marked severity. Our Board of Health, which is in many ways peculiar, claims the credit of all this good fortune, as due chiefly to their excellent sanitary measures. To this, the able editor of a local journal objects, going so far as to assert the utter incompetence of the Board.

In reality, the Board of Health is a disgrace to the city, but not more so than the rest of our municipal government. And in view of the qualifications (?) of

its members, there being not one medical man in it, the Board does very well. The Health Officer, who is the Board, is determined to occupy his office with credit, and is constantly urging the enforcement of sanitary measures throughout the city. If the cholera were verily in our midst the battle against it could not be more vigorous. The streets, although far from clean, are in better condition than they have been for several years, and the alleys are flushed out with an abundant supply of water, at frequent intervals; disinfectants are used in the garbage wagons, and a systematic inspection of premises is carried on by the officers of the Board.

One of the most commendable acts of the Board was the arrest and conviction, a few weeks since, of a professional abortionist. This case also served to illustrate the difficulties attending the conviction of such criminals, for although the guilt of the prisoner was unquestionable, it was proved with difficulty, and he escaped with a sentence which, for leniency, is a disgrace to civil justice.

Yellow Fever Notes.—The total number of deaths from yellow fever at Havana for the week ending August 2d, as shown by the weekly report of Sanitary Inspector Burgess, was forty, a considerable increase over the week previous.

Consular sanitary reports from Mazatlan, Mexico, dated July 22d, state that the number of deaths from yellow fever at that port during the months of May, June, and July, were four, eight, and fourteen respectively; estimated population 16,000. The Board of Health of Mazatlan held a meeting July 19th, inviting the attendance of foreign consuls, merchants, and inhabitants generally, at which it was decided to continue issuing clean bills of health to vessels touching at that port, for the present, inasmuch as the deaths from yellow fever reported were all of unacclimated persons; that as yet no resident had been attacked, and the cases being isolated and few in number, in proportion to the population of the city, and not having taken an epidemic or general character, it was not deemed justifiable to issue foul bills of health. The consul adds that steamers touching there bound for United States ports, exercise such caution in communicating with the port as is consistent with the safety of the ship and her passengers. It is not believed that the state of health at Mexican ports between Guaymas and Acapulco is proportionately better.

The United States Sanitary Inspector at Nogales, Arizona, states that the Spanish Opera Troupe, which passed through that place and lost some of their number by yellow fever, were detained twenty-four hours and disinfected.

The schooner "J. Taylor," from Porto Bello, with three cases of fever, probably Chagres, arrived at Cape Charles Quarantine Station on the 12th inst., one death having occurred two days previous. The sick were removed to the U. S. Quarantine Station, Fisherman's Island, and the vessel permitted to pass up to the Baltimore quarantine, in accordance with previous understanding with the Health Commission of Baltimore.

The Bellevue College Laboratory.—The authorities of Bellevue Hospital Medical College have filed plans for the new Carnegie Laboratory, which is to be built on the south side of Twenty-sixth Street, 75 feet east of First Avenue. The structure will be 50 feet square and five stories, or 70 feet, high. The cost is estimated at $50,000.

Koch on the Cholera Bacillus and on Pasteur's Criticism.—According to the *British Medical Journal* (August 2, 1884), Dr. Libbertz, of Frankfort-on-the-Main, who accompanied Dr. Koch to Toulon and Marseilles, published, during the week ending July 26th, a report of his experiences there, with the object "of correcting the numerous erroneous statements that have recently found their way into the columns of the daily press concerning the nature and propagation of cholera, and concerning the precautionary measures for the protection of individuals and the population at large." He sums up Dr. Koch's views in the following sentences: The spread of cholera is caused by personal contact, and not by goods and other objects, except damp infected linen. At the cholera congresses at Constantinople and Vienna, no case could be brought forward to oppose the accuracy of this view. The infective material is contained in the ejections, not in the urine, and not in the air we breathe. It is only efficacious in a moist state, dies when dry very speedily, and, therefore, cannot be transferred by the air. This explains why cholera bacilli have no permanency like those of smallpox. The latter are well known to form spores, a form of fructification of the greatest power of resistance. These spores can dry up for a long time, and become moist, and survive cold and heat; only a dry heat over 150° Cent., lasting for some hours, or a shorter process of steaming at 100° Cent., kills them. As above said, cholera bacilli do not possess the power of producing such lasting forms; they are known, by experience, to die after three hours' drying, and do not revive, as Pasteur strangely affirms, when again exposed to moisture. When Koch mentioned six days as the period after which objects that had been infected and then dried might be used again without risk, this was only to give a definite basis for practical purposes; he would have been just as well justified in naming one day. Pasteur's recent criticism, therefore, falls to the ground. Cholera is a disease which is confined to the digestive organs; cholera bacilli are not found in any other organs of the patient. It can only originate from the moist infective material forcing its way into the digestive channels. Contact with the patient is without danger, provided no contaminations take place likely to give infection from the digestive organs receiving some of the infectious matter. The following convey infection: infected drinking-water, infected water for washing and household purposes, infected moist and liquid articles of food. Amongst these, special stress must be laid on milk, and, above all, attention must be drawn to the power which dirty linen and the water it has been washed in have of conveying infection.

The Brown Institution.—Mr. Victor Horsley, B.S., Assistant Professor of Pathology in University College, London, has just been elected Professor-Superintendent of the Brown Institution, to succeed Dr. Ray, who was recently transferred to Cambridge.

DECORATION OF DR. KOCH BY THE FRENCH GOVERNMENT.—It is announced that the French Government has bestowed the order of the *Legion d'Honneur* on Dr. Koch, in recognition of his services in the cholera district rendered during his short stay in France.

A STATUE TO DUMAS.—A committee has been organized to collect funds for the erection of a statue to Jean Baptiste Dumas, in Alais, his native place, with M. Pasteur as President, assisted by MM. J. Bertrand, F. de Lesseps, and Cauvet, with 59 national members, 29 foreign, and 15 men of letters.

DEATH OF SIR ERASMUS WILSON.—A cablegram from London, dated August 8th, announces the death of Sir Erasmus Wilson, LL.D., F.R.S., the well-known and prolific writer on dermatology, and late President of the Royal College of Surgeons of England.

Professor Wilson was born in 1809, became a member of the Royal College of Surgeons in 1831, Fellow in 1843, member of the Council in 1870, and President in 1881. He founded the Chair of Dermatology, and the Museum of Dermatology in the College of Surgeons in 1869, and was elected the first professor. He also founded a chair of pathology in the University of Aberdeen, and made munificent gifts to hospitals. He took a great interest in Egyptology, and it was entirely through his munificence that Cleopatra's Needle was transported from the borders of the Nile and erected on the Thames Embankment in London.

NOTES AND QUERIES.

BIDDING FOR STUDENTS.

To the Editor of THE MEDICAL NEWS.

SIR: In your issue of July 19, there is an editorial that animadverts in strong terms of disapprobation ' to a practice of a Baltimore medical college of sending out, with its catalogue, a circular inviting the physicians receiving it to recommend young men for admission on certain 'special privilege terms,' which are set forth in the catalogue." The editorial further states that the "privileged student is admitted for half the usual fees, which, without the reduction, are less than those of first-class medical schools," and declares that "such unlimited bidding can only have the effect of degrading medical education and lowering the institution which adopts it in the eyes of the better class of the profession," etc. Since a member of the faculty—but not the dean—of our neighbor, the University of Maryland, has pleaded "not guilty" to your indictment, it is presumed that you refer to the College of Physicians and Surgeons, and I, therefore, most respectfully request space in your valuable journal to reply in behalf of that institution.

When the College of Physicians and Surgeons was established in 1872, it had become a practice for even what you term "first-class" medical schools to accept a number of students, on what was called the "beneficiary" plan, at rates less than their regular fees, while nearly all the schools in the West and South put down their fees to a much smaller sum than that charged in northern schools, and in many cases even below the beneficiary fees of those schools. The College of Physicians and Surgeons of Baltimore followed the fashion of the times, and accepted students at the reduced rate. Having determined to do this, they also determined to do it in an open, honest, manly, and business-like way. They first enclosed in their catalogues printed slips, and finally postal cards, containing a form of application for beneficiary scholarship which medical preceptors could fill up, and return to the dean, with as little inconvenience or trouble as possible, and thus save a good deal of troublesome correspondence and delay. In sending out these printed forms, we did not and *do not* consider that we are indulging in "unlimited bidding" for students, because we regard our professional brethren as honorable gentlemen who will be guided by the specifications of our catalogue, and will only recommend such students as are properly qualified and are entitled to aid on account of their want of means. We solicit no one to avail themselves of this privilege; we only inform them *how* they can do it, and furnish them with the blank forms to save trouble some correspondence. If it is no shame to accept students at reduced rates—and even such eminently respectable and "first-class" schools as the medical departments of the Universities of New York and of Maryland, and many others equally "first class" (according to their fee bills) announce in their catalogues their willingness to do so—it surely can be no more disgraceful to let preceptors and students know how they can avail themselves of the offer. Nor do we think that in doing this we are "degrading medical education," for we believe that that can only be done by granting diplomas to persons who have not qualified themselves for the practice of medicine. This practice, the College of Physicians and Surgeons has sedulously avoided in the past, as it will in the future.

In regard to the question of fees, which by implication you make a test of respectability, I find that there are in the United States eleven regular medical schools whose fees are higher than those of the College of Physicians and Surgeons; four others whose fees are the same: *sixty-four* whose fees are less; and of these last, thirty have established their regular fees at a sum less than our "privilege" fee. Some of these, as the medical departments of the Universities of Iowa and Michigan, whose equipment, teaching corps, and financial backing ought to entitle them to rank as "first class," have merely nominal fees. (See Fourth Annual Report of the Illinois State Board of Health.) But, after all, the fees charged cannot be accepted as establishing the right of a school to a "first-class" standing; for some schools whose fees are nearly, if not quite, as high as the highest, have virtually no means for teaching medicine practically, while some others, whose charges are the lowest, are thoroughly equipped in this respect.

I know of but one standard by which a school can be rated, and that is the standard of education which it offers, and the means and equipment which it possesses to enable it to maintain that standard. If judged by this standard, the College of Physicians and Surgeons of Baltimore is quite willing to submit to candid criticism, and even comparison with any school in the United States. It always has been, and still is, ready to coöperate in any feasible way with other schools to elevate the standard of medical education.

I am, very respectfully yours,

THOMAS OPIE, M.D.,
Dean of College of Physicians and Surgeons, Baltimore, Md.

August 9, 1884.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 29 TO AUGUST 11, 1884.

HEAD, JNO. F., *Colonel and Surgeon.*—Ordered to Portsmouth, N. H., to meet the Greely party, and consult upon the proper course of treatment, with a view to the entire restoration to health of Lieutenant Greely and the men of his command.—*Par. 14, S. O. 177, A. G. O.*, July 30, 1884.

WRIGHT, JOSEPH P., *Major and Surgeon.*—Sick leave of absence extended three months, on surgeon's certificate of disability.—*Par. 12, S. O. 176, A. G. O.*, July 29, 1884.

WOODWARD, JOSEPH J., *Major and Surgeon.*—Sick leave of absence extended six months.—*Par. 9, S. O. 178, A. G. O.*, July 31, 1884.

TAYLOR, A. W., *First Lieutenant and Assistant Surgeon.*—Ordered for temporary duty at Fort Riley, Kansas.—*Par. 1, S. O. 153, Headquarters Department of the Missouri*, July 29, 1884.

GANDY, C. M., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for one month, to commence between August 15 and 30—provided he furnish medical attendance at Fort Brady, Mich., during his absence.—*Par. 5, S. O. 154, Headquarters Department of the East*, July 30, 1884.

GIBSON, J. R., *Major and Surgeon.*—Granted leave of absence for one month and fifteen days.—*S. O. 36, Headquarters Division of the Atlantic*, August 4, 1884.

HEIZMANN, C. L., *Captain and Assistant Surgeon.*—Relieved from duty at Columbus Barracks, Ohio, and ordered for duty in Department of the East.—*Par. 2, S. O. 180, A. G. O.*, August 2, 1884.

MCCREERY, GEO., *First Lieutenant and Assistant Surgeon.*—Leave of absence extended two months.—*Par. 4, S. O. 180, A. G. O.*, August 2, 1884.

HOPKINS, W. E., *First Lieutenant and Assistant Surgeon.*—Granted one month's leave of absence, with permission to apply for one month's extension.—*Par. 1, S. O. 67, Headquarters Department of Arizona*, August 1, 1884.

VOL. XLV. SATURDAY, AUGUST 23, 1884. NO. 8.

ORIGINAL LECTURES.

VERSIONS AND FLEXIONS OF THE UNIMPREGNATED UTERUS.

A Course of Lectures delivered before the Boerhaavian Society.

BY ELY VAN DE WARKER, M.D.,

OF SYRACUSE, N. Y.; FELLOW OF THE AMERICAN GYNECOLOGICAL SOCIETY.

LECTURE II.

PATHOLOGY.

PATHOLOGICAL conditions are here grouped about the three most marked types of versions and flexions: the developmental, the acquired forms, and these errors as they present themselves at the termination of the menstrual life. These are divisions which are well defined by their pathological traits.

In their pathological relations, versions and flexions are considered together. Many authors hold that the separation of these conditions is unimportant (Goupil, Veit, Martin, Simpson).

Malignant complications are omitted, as having no special value in defining the morbid relations of versions or flexions.

A. Condition of the uterus in the developmental form of versions and flexions.

This form may not necessarily present changes in texture that amount to pathological conditions. Tiedemann found in this form, in several instances, no traces of anomalous or diseased conditions in the structure of the uterus. Scanzoni found, in a young woman, the mucous membrane, the vessels, and connective tissue intact. In its simplest form, this group presents a diminutive size of the body and cervix, without change in the textural elements of the organ. In connection with atrophy of the uterus, an arrest in the development of the ovaries and tubes has been observed (Breschet). Hueter endeavors to explain this arrest of development by assuming that there is such a defect in blood supply by change in the position of the broad ligaments, that circulation in the body of the uterus is retarded, and growth consequently arrested. The error in position and the atrophy become, under this view, mutually reactive to perpetuate the flexion. This theory receives some support by the specimens noted by Tiedemann and Jahn, of lateral or oblique flexion, in which the affected side, contrasted with the other, appeared defective in its evolution, both in length and mass, the tube upon the flexed side being also situated lower than the opposite one. This explanation fails when we consider those cases in which the uterus and its annexes exhibit the same degree of defective evolution.

The distinction between atrophy and arrest of growth in normal evolution must be observed. The term atrophy, when properly used, infers a diminished size from a previous state of normal development. In the conditions just described, atrophy does not exist, the normal size in formative evolution never having been reached. Here the flexion and the associated defective size are co-results of common causes.

Atrophy, however, plays an important *rôle* in the pathology of the developmental flexions. We may properly apply the term to those forms of the uterus observed by Martin and Hueter, in which ante- and retroflexion in young women and sterile wives were found associated with a very slightly developed and exceedingly movable cervix uteri. The assumption is more natural that these were cases of atrophy rather than of asymmetry of development. Rokitansky and Klob have observed the smallness and flexibility of the cervix in multiparæ and sterile women, connected with unequal thickness of the walls of the uterine body, and which these authors regard as true atrophy; as is proved by the observation in a case of anteflexion, in which the posterior wall, by its excess in thickness over the anterior, tended to perpetuate the flexion. Sommer found in the cadaver an anteflexed uterus less than two inches long, and atrophied to such a degree that a small probe could not be passed, except by force, through the canal of the cervix. Jahn notes like cases. Atrophy has in some instances become extreme. Mende notices a case of flexion observed in a young woman, in which the uterus was wholly atrophied. Dance observed a case of retroflexion in which the cavity of the organ was considerably enlarged toward the fundus, while the walls were very thin. Instances of eccentric atrophy, such as this, are of rare occurrence, except as a result of senile atrophic processes.

B. The term acquired—used to define a group of flexions or versions, implies an antecedent normal condition of development, form, and position. It is admitted by all authors of repute, Sommer alone excepted, that flexions due to the formative period of sexual life are defined from those due to other causes by faulty or asymmetrical development. The causes are here coincident with the forces of sexual evolution.

The division of the acquired forms into ante- and retroversion and flexion is deemed unimportant in a review of the pathological conditions (Duval).

Pathological phenomena will be arranged under three divisions:

a. Condition of the uterine parenchyma.

b. Changes in the uterine cavity.

c. Condition of near parts.

a. In recent cases, changes in the uterine texture are not always observed. This is undoubtedly true of all cases of versions. If we regard a condition of version as (Emmet) primary to that of flexion, the former becomes the initial change—a pathological point of departure in uterine tissue-changes. A condition already referred to, under its normal and etiological relations, is the theory of Rokitansky of the submucous connective tissue, which that author believes to be the supporting framework of the uterus. This layer of firm connective filaments is supposed to lose its sustaining power, and thus allow the organ to fold upon itself

While it cannot be denied that this layer suffers in the general impairment of the uterus necessary to the existence of a flexion, yet that the initial pathological lesion is confined to this tissue, to the exclusion of the uterine parenchyma as a whole, must be objected to. If the uterus, from a fresh cadaver, is pared of its mucous and connective-tissue lining, it loses but little of its resistance and elasticity, which seem to reside in the firm and dense muscular tissue of the organ. Catarrhal states of the uterine mucous membrane, which hold an important etiological relation to flexions and versions, cause a looseness and softness of the connective-tissue layer; this is not, however, any more marked than tissue-changes throughout the organ. In an endeavor to deal with facts, Rokitansky's theory must be excluded.

A condition found nearly as constantly in acquired flexions as atrophy is in the developmental, is an enlargement of the organ. In multiparæ, Hueter remarks that a hypertrophy of the organ connected with a flexion characterizes the acquired form. This hypertrophy is generally associated with serious changes in the muscular substance of the uterine walls. Martin has noticed cases in which the parenchyma was so relaxed that the organ would bend upon itself, first in anteflexion and then in retroflexion. The antithesis of this condition is observed in those cases in which the uterine tissue is so firm that on replacing the organ it would instantly recoil to its flexed position. Relaxation of uterine tissue is not always general. The point at which this is most frequently observed is at the os internum. In the normal organ, this is the weakest part of its walls. Here the displacing forces exert the greatest strain—a sort of fulcrum upon which these forces exert their leverage. Relaxation of the walls at this point is of great pathological value in connection with rapidly acting causes. In cases of flexion following abortion or lying-in, the uterus is found enlarged, its walls softened, the cavity extended, the mucous membrane denuded—even the muscular substance laid bare; while the fatty metamorphosis and involution of the organ are in abeyance. Guerin states that where abortions hold this etiological relation to flexion, inflammation is the direct cause of changes in the parenchyma, or of arrest in the physiological restitution of the organ. But, in cases in which the inflammatory process has a narrower field—as in the non-puerperal uterus—it is a very constant condition. It is rare to find a case of acquired flexion in which the body of the uterus is not sensitive to the touch, be the wall hypertrophied or condensed. Kiwisch and Martin have found these displacements associated with endometritis quite generally. This is commonly found connected with the corporeal tenderness. Israel states that the origin of this inflammatory condition is to be sought in lesions after abortion or labor, or in circumscribed inflammations either in the uterus itself, or through the transplantation of the inflammation from the vagina to the neck. After such inflammatory processes, cicatricial thickening, with shortening in isolated groups of muscle-fibre, is observed; so that the opinion seems justifiable that, as in other organs in this condition deformities are produced, so in the uterus the same consequences may be anticipated. Guerin supports this theory by stating that from inflammation and resulting shortening of muscle-fascia, a permanent deformity may be caused.

Dr. Squarey believes that in the acute flexions, so called, the uterus gradually falls over into a flexed or verted position, owing to loss of tone in its tissues, the organ being too weak to uphold the fundus. There is no necessity to ascribe its position to pressure from above; the organ once being flexed, its size and atony are sufficient to keep the uterus in its abnormal position mechanically. In the fatal case of anteflexion of Dr. Walshe, recorded by Ashwell, the post-mortem examination showed the uterus soft, flabby, and yielding at the angle of flexion; the anterior and posterior walls were one inch thick. This accords with Hueter's idea of the walls in inflammatory hypertrophy. Rockwitz has noticed a similar condition in flexions following parturition. As already noticed in the lecture on etiology, Martin has traced various pathological conditions of the walls of the uterus leading to ante- and retroflexion, to subinvolution of the placental site. In these cases the inflammatory processes play an important part. The walls of the organ at the seat of placental insertion are thickened, spongy, and yielding; but it is necessary to conceive of the uterus generally having more or less of the same character, less, possibly, the thickening of a circumscribed area, in order to understand the manner in which a flexion could be a primary result. In these cases, if the relaxation of the organ is limited to a particular spot, flexion is preceded by version, the former supervening on a progressive impairment of the sustaining power of the uterine parenchyma. Notwithstanding the well-known ability of Martin as an observer, the matter is somewhat open to doubt, that the seat of the placenta, retaining, as it must, a lingering involution process under even normal conditions, has less to do with the production of flexion than a general impairment of the resisting power of the uterus. Many facts may be adduced to prove that the impaired tone of the uterus is general rather than confined to a single point. In old cases the submucous connective tissue at the os internum shows a marked degree of relaxation, but the whole uterine parenchyma is softer and less elastic, which is simply in a more evident condition at the flexed point. At this point yellow spots of fatty degeneration have been observed (Scanzoni, Tilt, Hodge). Hewitt has observed a loss of resistance and softness of the whole uterus in women who have suffered from chronic nutritive disturbance, leading to a pliability that results in flexion. In slight general relaxation of the walls of the uterus the encurvature shows itself as a folding or angular notch in the wall involved. Sommer has ventured the opinion that a pathological element of flexions is connected with a rheumatic condition of the uterine wall—a muscular rheumatism, in fact, which, in the absence of any demonstration that the muscular texture of the uterus is susceptible to the rheumatic inflammation, must be classed with the theory of another German writer that flexion is sometimes due to a condition of cramp or tonic spasm of the muscular fibres of the flexed wall. Connected with the hypertrophy of the uterus, Israel describes a condition of œdema of the walls which he ascribes to a condition of venous stasis of the parenchyma (Stauungshyperämie). The same condition he has noticed in versions, especially in a high degree of the displacement backwards, in which the fundus of the uterus, by pressing upon the venous plexus upon the posterior pelvic wall, caused an œdema

of the lower uterine segment. It is doubtful if veins situated upon the posterior pelvic wall have a sufficiently close connection with the venous system of the uterus to cause a blood stasis and serum exudation into the connective tissue of the organ. It is probable that the observer mistook the softened hypertrophy of the neck for a state of œdema.

The hypertrophy of the uterus has two relations to the flexion and version of the organ, namely, an inflammatory hypertrophy, which holds a causative relation to the flexion, or is either developed, intensified, or perpetuated by the venous hyperæmia caused by the obstruction to the return of blood at the point of flexion (Hueter). But the venous stasis may be due to a more widely prevailing cause. According to Klob, the current of blood out of the uterine veins to the vena hypogastrica is interrupted, and, in consequence, the collateral hyperæmia produces oftentimes a considerable expansion of the plexus pampiniformis, since the blood cannot all flow through the spermatic vein. While this interruption of the circulation is of importance to the organs which lie near the uterus, yet the direct effect is more disastrous to the parenchyma of the uterus. In the first condition, that of stasis due to the angle of flexion, the uterine segment below the angle was the chief seat of venous hyperæmia, since the uterine cervix and body have, in a measure, separate or supplemental avenues of blood-escape. In the hyperæmia caused by tension of the broad ligaments and the connective-tissue supports of the uterus, the hyperæmia is general throughout the organ. While the uterus may suffer generally through its mass from the evil effects of the impeded circulation, yet the permanent result is not equally distributed through both walls. The flexed wall at the angle of displacement remains either stationary in thickness or slowly atrophies, while the opposite wall and the fundus undergo an interstitial hyperplasia that renders the displacement of the organ permanent.

Scanzoni graphically describes the condition of the uterine parenchyma and cavity. On section of the uterine walls, a livid and, many times, a dark-green color is observed, a condition which permits the conclusion that the interior of the uterine walls is in a state of chronic stasis and associated always with a more or less considerable volume and increase in the weight of the uterine body. Depending on the duration of the displacement, the walls of the uterus may be found either thick, stiff, and resistant, or the opposite—elastic, yielding, and loose, with the vessels turgid with blood; briefly, it shows the different stages in the development of tissue-changes in the so-called chronic corporeal metritis. The cavity of the uterus appears generally considerably enlarged; oftentimes it is filled with water-like, thin-flowing fluid, or a somewhat viscid, yellow or bloody mucus is observed. The contents of the organ are explained by Scanzoni as depending on catarrhal hypersecretion of the mucous membrane, and partly, that at the point of flexion the contact of the anterior and posterior walls of the cervix causes an arcuation of the canal, and prevents or retards the escape of the uterine secretion.

Hewitt and others speak of a marked induration, without atrophy, associated with chronic flexion. In this condition of the walls of the organ there is marked resistance to the replacement of the uterus by the sound, and the part quickly recoils to its dislocated position on the withdrawal of the replacing force. The indurated wall seems built up of hyperplastic tissue in its position of flexion, and thus resists powerfully any attempt to straighten or replace the uterus.

Rokitansky first called attention to the fact that in old women who have suffered for a long time with flexion, and who have borne many children, there is found, in the anterior periphery of the os internum, and embedded in the uterine substance, a large vein. Klob notices an instance in which this vein was 1.5 line in diameter. Martin explains this venous dilatation by the compression of the uterine vessels, resulting in increased blood pressure. This explanation removes this condition from its etiological relations, and places it among the results of long-continued flexion in an organ previously over-burdened by an excess of functional activity. Hueter, however, fancies that its relation to flexions is etiological, and by means of which the uterine parenchyma is compressed, and the uterus thus more easily flexed.

Atrophy, like hypertrophy, may not be a result of flexion or version long delayed. Martin speaks of it as one of the changes that take place rapidly, but mentions it as connected with a condensation of uterine tissue. This condensation is as frequently observed above as below the seat of the flexion. Without any attempt at explanation, Martin asserts that this condensation is observed above the seat of flexion, generally as a result of defective involution of the placental site after parturition with a flexion existing. That Martin makes any distinction between atrophy and condensation is disproved by a remark in the context of the above, in which he states that similar conditions are found below the point of flexion, although "it by no means always follows that the cervix is swollen; on the contrary, it is often flattened or compressed." The lower portion of the uterine neck is often considerably compressed and now and then elongated, particularly in cases in which granular erosion is at the same time existing (Huguier). The point of flexion in most cases does not always show tissue-changes; but, in cases of longer standing, the walls at this point become atrophied and show well-marked cells. In young women suffering from flexion while the muscular tissue, the vessels, and connective tissue appeared wholly intact, yet fatty particles were observed on a cross-section (Robin, Scanzoni, Virchow). Changes occur very early at the point of flexion in which the mucous membrane, apparently from compression, becomes white and fibrous, and the os internum surrounded with small cystic follicles at those points where the mucous membrane remained unconverted (Virchow, Martin). Hewitt regards atrophy at the seat of the flexion as a result rather than a cause of the uterine malformation. According to Virchow, the point of flexion on the wall involved becomes more atrophied as the muscular tissue disappears, until not a sign of connective tissue remains. Tilt states that the uterine parenchyma at the inner os becomes atrophied to a fold in old cases of flexion. West and Dumpe have verified the atrophy of the flexed point of the uterine wall, and the consequent shortening of that side of the organ. Rokitansky has noticed a growing together of the uterine cavity at the angle of flexion, associated with a scar-like contraction of the connective-tissue structure.

As a prelude to this adhesion, we have a close contact of the mucous surfaces at the seat of flexion intensified by the gradual atrophy of the uterine walls, by means of which adhesive inflammatory action is induced. Scanzoni found in the highly atrophied uterus of a young woman, who had never menstruated, an atresia at the seat of flexion. In one case the same observer found a stenosis, in consequence of which the region of the os internum was so narrowed that it was only by the employment of considerable force that a small silver sound could be introduced. So far as known, all cases of atresia and stenosis of the uterine canal at the flexed point are associated with atrophy and condensation of the uterus generally.

Scanzoni states that he has found the uterus at, and in the near neighborhood of, the flexion generally flattened antero-posteriorly. Virchow has noticed the same condition extending throughout the uterine neck. His explanation that this is due to pressure of the rectum distended by feces is hardly sufficient. If this were so, the condition is one that ought to be very commonly observed, instead of being usually associated with flexion. It is more rationally explained as the result of tissue-changes due to the embarrassed circulation of the organ, in which the resultant atrophy assumes an antero-posterior symmetry, the organ being originally flattened in that direction at the angle of flexion.

The condition of the vaginal portion of the cervix in versions and flexions gives rise to some difference of opinion. Martin states that from the flattening of the cervix, already described, the os externum becomes obstructed. So extreme may this become, that by preventing the escape of mucus from the canal of the neck that cavity may undergo a sack-like enlargement (Hueter). The condition of the os externum is usually described as patulous. This is supposed to be characteristic of the state of the uterine mouth in flexions. Scanzoni states that he has found the external os considerably open in those who have never borne children. Hueter says that he has been unable to make a verification of this. He has never found the os externum patulous except in multiparæ. Scanzoni explains this condition of the external orifice by the theory that the posterior wall in anteflexions, and the anterior wall in retroflexions, while enlarged and heavy, exert a traction over the cervix and draw the external mouth open. It is difficult to conceive of the cervical wall exerting any such power over the circular fibres of the external opening. Hueter's objection to the theory of Scanzoni, that the anterior and posterior lips are of equal thickness, does not always hold true. It is not unusual to find that in retroflexion the anterior lip and in anteflexion the posterior differ widely in thickness; this is a condition that typifies the atrophied state of the wall involved in the flexion. We may premise that this patulous state of the external opening is a characteristic of the acquired flexion, and never met with, except in the most exceptional way, in the developmental flexion. It is not a condition of atrophy, either general or partial, of the uterine walls. It may be explained by known conditions of the walls in acquired flexions. The patulous state of the os externum is rationally explained by, first, a general or partial relaxation of the muscular fibres; by interstitial hyperplasia of the labium of the uninvolved wall, in which the enlarged and relaxed parts find space for development by an increase of the periphery of the os externum; by an irregular fatty degeneration of isolated bundles of longitudinal muscle-fibres. The relaxation of the circular fibres of the vaginal portion of the cervix is sometimes nearly complete, as in the condition of ectropium (Roser) of the os, in which the mucous membrane of the cervical canal seems to be continuous with that of the vagina. A parturient accident that is very common, a laceration of one or both lateral walls of the vaginal portion of the cervix, is often found associated with flexions (generally retroflexion), and in this state of the cervix a more or less complete eversion of the external opening is observed.

The margins of the os externum are often in a state of granular ulceration (Heywood Smith). Papillary hypertrophy, and occasionally deep corroding ulcers, have been observed (Scanzoni, Rockwitz).

b. The condition of the uterine cavity in flexions and versions presents many uniformities. One of the most common conditions is that of catarrh of the mucous membrane. Seyfert has stated that he rarely observed a catarrhal state of the uterine lining in the dead subject (Hueter); but many of the minute pathological changes, that in the living might be expressed by hypersecretion, could easily escape detection in the cadaver. Rokitansky, as has been already noticed, regards a catarrhal condition as etiological, while Klob states that it may not always be a condition primary to the flexion. The following considerations render the idea of Klob a rational one. The catarrh may exist as an accumulation in the cavity of the organ, and as such may antedate the flexion; or, the catarrh not existing as a hypersecretion, but in consequence of pressure on the inner os, or from distortion of the uterine connection with the neighboring parts, causing a passive hyperæmia in the flexed part, which must develop a hypersecretion of the mucous membrane, and in both cases cause an expansion of the cavity.

An examination of the secretion of the uterine cavity is confirmative of the latter of the above conditions. The increased secretion is frequently observed to excoriate the vaginal portion of the uterus and the vulva, and sometimes quite a degree of vaginitis is noticed. An examination of the uterine secretion, taken from the os externum, under the microscope, shows a predominance of pavement epithelium in different degrees of degeneration, a fact which proves that the greater part of the discharge comes from the lower part of the uterine canal. Normal cells were rarely observed; the majority of the cells were in a more or less advanced stage of fatty degeneration, with granular particles interspersed. In many the cell membrane had vanished, leaving granular masses, in which the original contour of the cells was preserved. Among these elements cell nuclei, also in a state of degeneration, were observed, as well as pus cells and the débris of granular erosion of the os externum. The following figure, copied from one in Beizel's *Die Krankheiten des Weiblichen Geschlechts*, Bd. ii. p. 209, represents the discharge removed from the os externum of a retroflexed uterus.

Martin states that it is not rare to find in the tract of a flexion traces of recent or chronic inflammation of the mucous lining, such as red, rounded, or flattened granulations, which obstruct the opening of the os internum.

Friable and granular swelling of the mucous membrane may be seen throughout the cervical canal. As a result of the hypersecretion of the mucous follicles, their cavities become disintegrated and undergo a cystic

generation—the so-called ovula Nabothi. These morbid processes in the mucous lining, added to contraction and compression at the seat of the stricture, occasionally result in such a contraction of the lumen of the canal that retention of menstrual discharge, mucus, and pus occurs. From this cause the uterine cavity has been observed enlarged (Hewitt). Scanzoni found, in a woman thirty years old, who had suffered from flexion, about two ounces of fluid and coagulated blood. Virchow has observed the mucous membrane, at the seat of flexion, degenerated into a white, fibrous layer, and the internal orifice surrounded with small cystic follicles. Martin has seen such a condition extending 2 cm. above and below the flexed point. This destruction is not limited to the mucous membrane, but the submucous connective-tissue stroma is sometimes exhausted (Rokitansky). In attempts to repair these lesions star-like contractions result.

These pathological changes are confined, in a great measure, to the acquired forms of flexion. In the developmental versions and flexions when pathological conditions, such as are here described, occur, they are generally sequelæ, and not primary to the uterine displacement. When these are observed in connection with the last-named group of flexions, the causative relation may be traced to retarded circulation and resulting hypostasis. In fact, many of the pathological phenomena described may be deemed sequelæ of flexions in general rather than antecedent conditions. The evidence that suggests this may be found in the fact, that acquired retroflexion is rare in nulliparæ, occurring only when, by reason of long-continued catarrh, the uterine texture has lost its resistance; anteversion takes place with an abnormally dense and swollen uterus, the antithesis of the former, while anteflexion occurs in multiparæ oftentimes with an absence of any marked pathological changes (Schrœder).

c. The conditions of near parts in cases of versions and flexions of the uterus are of great interest. Flexions are rarely found except in connection with other changes which are present, either in the ligaments, connective tissue, and vessels, or in the vagina, bladder, and rectum.

Pathological conditions of the ligaments of the uterus were described in the lecture on etiology; yet, these frequently bear a secondary relation to the change in position. An anteflexion associated with inflammatory shrinking of the lig. sacro-uterina might justly be assumed to be a result of the displacement, while the same condition in a retroposition of the uterus, with retroversion or flexion, could with equal justice be regarded as causative. The outer surfaces of the versed or flexed uterus are frequently the site of membranous exudations binding the uterus to its neighboring parts—the bladder or the rectum—and which are, without doubt, produced after the faulty position of the uterus was assumed. Martin describes a case which clearly shows this; in this example the posterior surface of the uterine body and the fundus were bound to the sacrum by pseudo-membrane, but also the forward wall of the uterus sent out membranous fibres to the bladder in front, and laterally to the lumbar vertebra. In other cases the remains of old inflammatory exudations and cicatricial swellings are found upon the peritoneum which covers the uterus. Martin coincides with Virchow in the opinion that the shrinkage of these pseudo-membranous fibres causes version of an otherwise healthy uterus, flexion being produced afterwards as the result of impairment of the uterine parenchyma.

What Martin regards as a rare complication of flexions is an approach and fixation of the isthmus uteri to the pubes, and which, he believes, depends upon a contraction of pubo-vesico-uterine ligaments. This shortening may depend upon either a pericystitis or a parametritis-coli, or on a resorption or suppuration of a hæmatoma. This observer has noticed an inclination of a flexed uterus to one side, due to the development of cysts or tumors in the tube or ovary, and to which the uterus has either contracted adhesions or been drawn from its median position by a shortening of the ligamentum ovarii. Generally, however, the inflammation and subsequent contraction of the exudate has been detected in the broad ligament, and the result is a latero-version with a retroflexion or version. Frequently versions and flexions are found connected with tumors either in the uterine wall or in near parts, the connection of which, by adhesive inflammation, is evident.

From pressure of the displaced fundus uteri, and from drawing or stretching of the peritoneum covering the uterus and near parts, slight local peritonitis is produced, with its attendant pseudo-membranous adhesions. Hueter states that it is not rare to find in the depths and expansions of the vesico- and recto-uterine folds traces of a previous inflammation in the shape of partially organized exudation masses of an elastic feel, livid, and sometimes of a dark-green color. Rockwitz says that he has found these adhesions so elastic that after the uterus was replaced the organ would recoil back to its original position of displacement with an evident jerk.

Now and then flexions or versions may be found associated with right or left latero-version, caused by

shrinking of cellular tissue after inflammation and abscess. These pathological conditions have already been referred to in the lecture on etiology. Ludwig Joseph has reached the following generalization concerning the connection of the pathological conditions of near parts and of the uterine parenchyma with the different forms of flexion; thus, anteflexion, when not developmental, is frequently associated with perimetritic adhesions, while retroflexions depend generally upon relaxation of the uterine substance in consequence of defective puerperal involution.

The position of the rectum to the left has an influence on the direction of retroflexion. Klob has explained the general reflection of the uterus to the left in this displacement by an unequal length of the round ligaments; but Hueter advances the idea that during violent efforts at defecation the expulsive efforts of the abdominal muscles are concentrated around the rectum to the left, the uterus being also affected, undergoes a slight torsion movement in that direction.

The interruption of a free circulation through the pelvic venous system in versions and flexions is of importance to organs near the uterus. Varicose enlargements have been found in the hemorrhoidal and vesical veins, resulting in chronic catarrh of the rectum, bladder, and urethral mucous membrane. Hyperæmia and œdema of the ovaries have been observed (Klob). Chronic oöphoritis has been found associated with uterine flexions (C. Mayer, Hensley, Martin).

In long-standing cases of version and flexion the neighboring peritoneal pouches suffer essential changes, particularly the vesico-uterine and the recto-uterine folds. A case has been observed in which the uterus was pressed through the posterior vaginal wall as a hernia vaginalis (Martin). Manuel describes two cases of retroflexed uteri lying in the prolapsed recta; and another case in which the retroflexed organ had formed adhesions with the perforated rectal walls (Rokitansky). Hueter refers to a case in which retroflexion existed to such a high degree that the posterior vaginal wall was protruded into an invagination of the anterior rectal wall, and this, containing the uterus in a relaxed condition, was found out of the anus. A remarkable case of prolapsus uteri, complicated with retroflexion, has been recorded by Schott, in which there was perforation of the vagina at the posterior cul-de-sac (Hueter). Freund reports two cases of retroflexion of the uterus, in which the cervix passing upward compressed the ureters, and thus induced hydronephrosis. Bamburger reported a case that may help to clear up any error in observation on the part of Freund; this related to a retroflexed pregnant uterus at the fifth month, in which the organ compressed the ureters, and a fatal state of uremia ensued. Hueter believes that a considerable stretching of the uterine connections may lead to this pathological state.

c. Condition of the flexed or versed uterus at the climacteric period.

With the discontinuance of the menstrual process the blood-turgescence, which had been a leading trait of functional uterine life, vanishes, and with it a diminished supply of blood to the uterus. The result is a gradual atrophic condition of the parenchyma of the organ. So long as the external or internal os remains pervious the atrophy is concentric, that is, the uterus and its cavity appear proportionately reduced in size (Hueter). A continuance of the atrophic process may be observed in the muscular substratum, which appears thinner and more yielding. Senile marasmus, according to Klob, is total, the uterus is very small, ante- or retroflexed, and is oftentimes rough and granular to the touch. In the annexes the arteries may be seen in many places small and serpentine in their distribution. The subperitoneal arteries of the uterus become stiff and convoluted, and project upon the surface in hard prominences. On section the substance of the uterus appears pale-green or dark-red, and on a cross-section the stumps of arteries project as small, white points, thickened in their walls, and often calcareous. The mucous membrane is loose, thin, white, or in a condition of so-called atrophy of a deep-red color, which sometimes pervades the parenchyma. At other times it is seen studded with small cysts; and again, it is reduced down to a serous, shining stratum of connective tissue (Hueter).

The vaginal portion appears small and short, and even wholly disappears, so that upon the vaginal vault small folds reveal the external opening of the cervical canal.

Frequently the atrophy of the uterus exists in connection with fibroids, and in a few of these cases the place of the uterus is found occupied by the convolutions of a rounded, fibrous mass, and among them scarcely a trace of the muscular tissue of the uterus is to be found. The cavity has been observed to be wholly wanting, or is represented by a small cavity, found somewhere among the convolutions, filled with gelatinous mucus. The cervix may be normal or elongated. In the case of fibroids with calcareous degeneration, the uterus has been observed to be atrophied to a thin skin-like framework (Hueter).

When a condition of stenosis or atresia exists at the inner os, senile atrophy is eccentric, that is, the cavity of the uterus becomes enlarged and its walls thin. In this condition of the os internum the secretion of the uterus is either retained or obstructed in its discharge, and leads to a condition of hydrometra.

The stenosis or atresia of the inner os is oftentimes the result of mechanical causes, such as that due to close contact of the mucous surfaces at the point of flexion. Such a case is reported by Kiwisch, and observed by him in the cadaver. Virchow notes a case somewhat similar, in which an organic stricture existed at the os internum, as the result of inflammatory thickening of the mucous membrane (Hueter). According to Scanzoni, atresia at the internal orifice in flexions may be caused by senile atrophy or shrinking of the connective tissue, or in consequence of chronic catarrhal inflammation accompanied by erosion of the epithelium of the mucous membrane of the cervical cavity, so that complete adhesion of the surfaces in contact occurs. Scanzoni found, at the post-mortem examination of two old women, a high degree of flexion, accompanied by complete atresia at the point of flexion. One of these cases showed eccentric atrophy; the other, observed in a woman over seventy years of age, the quantity of accumulated mucus in the cavity of the uterus exceeded half an ounce.

The advance of senile atrophy is favored by the presence of chronic catarrhal inflammation. In consequence of this, mucous or cystic polypi may be found

combined. Atrophy of the uterus has been noticed associated with that of the ovaries (Hueter). Klob states that in senile atrophy, with incomplete atresia, it is not unusual to find the uterine cavity enlarged to the size of a hazel-nut, and filled with a glue-like mucus. This is an instance of eccentric atrophy of the uterus, due to defective power of contractility in the uterine walls.

Atrophy of the walls of the organ result in consequence of the enlargement of the cavity through the accumulation of mucus, which is sometimes considerable. Kiwisch reported a case in which the uterine cavity contained two pounds of fluid. In considerable enlargement of the cavity the mucous membrane becomes thin and degenerated. Its soft, velvet-like feel is lost, and the membrane assumes the smooth and shining appearance of a serous coat. In the larger expansions of the cavity the mucous membrane is of a reticular structure at times, or is now and then reduced to a lamella of connective tissue, covered on its inner surface with cylindrical epithelium, which has, in nearly all cases, lost its cilia (Hueter). The glands of the mucous membrane are diseased from the beginning of hydrometra, with fatty degeneration of their epithelium, and end by producing gaps in the mucous lining of the organ. Cystic degeneration of the utricular glands has been noticed.

ORIGINAL ARTICLES.

ON THE PROGNOSTIC VALUE OF THE LOCAL MANIFESTATIONS OBSERVED IN TUBERCULOSIS OF THE LARYNX.[1]

By J. SOLIS COHEN, M.D.,
OF PHILADELPHIA.

As the duration of chronic tuberculosis of the larynx varies within limits extending from six months or thereabouts to as many years or more, it would be desirable to ascertain whether there are not some lessons to be learned from its laryngoscopic study which will enable us to predict, with some degree of assurance, the probable period to which, in any individual instance, life may be prolonged. This is the inquiry proposed to the Section in this communication.

While it may be admitted that recovery takes place in some instances of tuberculous laryngitis, it remains doubtful whether there are any characteristic laryngoscopic manifestations which justify the prediction.

Those cases which have been shortest in their career, have appeared to me to have accompanied cases of pulmonary tuberculosis in which caseation has taken place rapidly. Although both the functional and the physical symptoms have sometimes become manifest in the larynx some weeks or some months before they have been detected in the lungs, there has been no reason to doubt that the involvement of the larynx has actually been secondary. The patients have lived for periods varying from six to eighteen months after the first onset of laryngeal symptoms.

The earliest laryngoscopic picture is one of congestive catarrhal laryngitis merely. Essentially uninfluenced by treatment, the picture commences to change in the course of a few weeks by the addition of one or more series of minute ulcerations of the mucous membrane; their site being upon the posterior surface of the upper portion of the epiglottis far more frequently than in any other locality. As the case is examined from day to day, or at intervals of a few days, it is seen that these ulcerations gradually extend in depth and in periphery; and when they are close together, two or more of them will coalesce. There is no pus on their surface. In some cases gradual intumescence of the epiglottis takes place, and in many of these instances similar swelling of the ventricular bands and of the vocal bands follow. In a few of them the same sort of swelling is seen to be going on in the interarytenoidal and in the aryteno-epiglottic folds. While the swelling is progressing, the ulceration continues to spread, so that the internal surface of the larynx may be eventually mapped out by irregular ragged ulcers, in some instances involving almost the entire circumference. This ulceration being in part suppurative, pus may be seen upon the surface. Excessive granulations, presenting the aspect of independent neoplasms, are sometimes developed around the edges and beds of some of these ulcers. Destructive ulceration of the epiglottis ensues in some instances, usually from above downwards, but exceptionally from the side toward the centre.

The prognostic differentiation of this series of pictures is indicated chiefly by the initial hyperæmia, the multiple ulcerations, upon the epiglottis especially, and the tumefaction in the anterior portions of the larynx, followed by progressive ulceration both tuberculous and suppurative. Ulceration limited to the epiglottis indicates unusual rapidity in the course of the disease. Ulceration limited to the interior indicates a more sluggish course. The rapidity with which the ulceration extends influences the prognosis proportionally.

A second series of cases live from two to four or more years after the involvement of the larynx. They appear to me to be cases of sluggish tuberculosis of the lung which has begun in localized pneumonitis. The involvement of the larynx does not take place until the disease has made considerable progress in the lung, often not until softening has occurred, or is about to begin.

The earliest characteristic laryngoscopic picture of these cases is one of pallid mucous membrane, in marked contrast to the congested mucous membrane of the first series. There are no early minute ulcerations as in the other series. As the larynx is inspected from time to time, its features are seen to be losing their marked outlines and to become more and more tumid. The sharp borders of the aryteno-epiglottic folds, of the edges of the ventricular bands and of the vocal bands, are seen to become thickened; and circumscribed tumefactions take place at those portions most abundantly sup-

[1] Read for Dr. Cohen before the Laryngological Section of the International Medical Congress, Copenhagen, August, 1884.

plied with lymphoid cells. This tumefaction is most frequent and most constant over the supra-arytenoid cartilages and within the aryteno-epiglottic folds. In many instances, however, it takes place within the interarytenoid fold, and in some instances in the epiglottis. The peculiar outlines of the supra-arytenoid cartilages become lost in the well-recognized characteristic pyriform tumefactions which taper along the aryteno-epiglottic folds, toward the epiglottis; while obliteration ensues of all lines of demarcation between the folds proper and the outlines of the cartilages. The tumefaction in the interarytenoid fold is usually diffuse; sometimes it is in a single hemispheroidal mass; less frequently it is acuminated; in either instance preventing approximation of the vocal bands.

In some instances the epiglottis becomes thickened to several times its normal dimensions, so that it fails to occlude the larynx in deglutition. Collateral œdema sometimes adds to the tumefaction in the aryteno-epiglottic folds and to that in the epiglottis. These tumefactions may continue, to the end, the sole laryngoscopic manifestations. In advanced cases, however, ulcerative processes, sometimes extensive, often take place in almost any portion of the interior of the larynx; even in those rare instances of subsidence of the pyriform swellings. When located posteriorly, they are indicative of a prolongation of the process. Occasionally, indeed, ulcerations of limited extent cicatrize temporarily or permanently, life remaining prolonged for several years.

The chief prognostic differentiation of this more prolonged form of the disease, resides in the pallor of the mucous membrane, and the subsequent circumscribed tumefactions at the posterior portion of the larynx.

It would be superfluous before this assemblage to detail the entire physical history of a tuberculous larynx. Without having anything new to offer, the object has been to invite a discussion as to whether the indications alluded to, or any others, are sufficiently distinctive to justify the predication of a prognosis as to the probable tenure of life in the early stages of any given case of tuberculous laryngitis; and whether the shortening of life in the first group of cases is simply due to innutrition following the dysphagia attendant upon disease of the epiglottis and the superior margin of the larynx, irrespective of the march and situation of the tuberculous processes. Reliable answers to questions as to the probable length of life in tuberculous laryngitis may be of great importance to the patient and to his family.

A STUDY OF INEBRIETY COMING FROM INJURIES OF THE HEAD AND BODY.[1]

By T. D. CROTHERS, M.D.,
SUPERINTENDENT OF WALNUT LODGE, HARTFORD, CONN.

The fact has only recently been recognized that injuries of the head and body are not unfrequently followed by profound and excessive use of alcohol. An outline history of such cases may be stated as follows: Persons who are previously temperate, or, if not total abstainers, are only moderate or occasional drinkers, will suffer from injury to the head, generally blows, fractures, concussions, or fracture of other bones of the body, contusions, wounds, or hemorrhage, and from this event, or immediately following convalescence, will begin to use opium or alcohol to great excess, falling rapidly into chronic conditions. Such persons are unable to give any reasons for their drinking, other than that they need spirits, and rarely ever make any effort to recover. A state of general paralysis of the will, and hopeless melancholy of the future, appears in most cases. In some cases spasmodic endeavors to be temperate are made, but generally fail, leaving the victim more prostrated and helpless than before. In some cases acute mania appears and they are placed in insane asylums, from which partial recovery follows, but from the time of discharge they relapse, using more spirits than ever. Dementia, general paralysis, or some acute disease soon follows, terminating in death.

In other cases a temporary subsidence of the drink-craving is marked by a total change of character and motive. Criminal and pauper tendencies come out prominently, and a disregard of duty and obligations to others, and a disposition to extreme selfishness and secretiveness, take the place of former opposite traits of character. Many such cases appear in courts, and the impression of the judge and jury is that their previous good conduct makes the present state more culpable and heinous. Both in jail and in insane asylums the so-called moral state of the victim obscures every other condition, and rarely, if ever, is any study made of his case. *The frequency of these cases can only be determined approximately*, because no study of them has been made. Dr. L. D. Mason, of the Inebriates' Home at Fort Hamilton, New York, in a general etiological study of six hundred cases, under treatment at that asylum, found that sixteen per cent. came directly from head injuries. Dr. Day, of Boston, in a study of two thousand cases under his care at the Washingtonian Home, found twenty per cent. traceable directly to injury of both head and body. In a history of over four hundred cases under treatment at Binghamton, New York, and at Walnut Lodge, in Hartford, Conn., which I have obtained, nineteen per cent. were clearly due to traumatism. This does not include those obscure cases of psychical traumatism which I have studied in detail, and published in the *Journal of Mental and Nervous Diseases*, and elsewhere, the frequency of which is not yet ascertained. So far, these are the only facts from which to infer the percentage of cases from this cause, that I am aware of.

This effort to trace some of the facts concerning the influence of traumatism as a cause of inebriety, I believe to be the first in literature. Forbes, Winslow, Bucknill, Maudsley, Brown, Watson, and many other eminent English authorities have mentioned such cases, and several continental writers have described them in connection with some form of insanity. But the general recognition of inebriety in medical literature is so vague and uncertain, that these cases have attracted no attention.

[1] Read at the Annual Meeting of the Association for the Cure of Inebriates, at New York City, 1884.

I propose to group some of the facts which appear from the general history of the cases under my care coming from this cause. Unfortunately, the data are imperfect, and only include some general notes, which will become landmarks for further and more accurate study in the future.

Of the 67 cases of inebriety dating or beginning from injury, which I have recorded, the following statement represents the condition noted on admission to the asylum.

16 cases were periodical dipsomaniacs.

10 cases were irregular dipsomaniacs.

18 cases were periodical inebriates.

15 cases were irregular or steady inebriates depending on circumstances.

11 cases were irrregular, impulsive inebriates, with criminal tendencies, and without any conception of duty and obligation to others.

6 cases were of that exhausted anæmic class in which inebriety seemed but an accidental phase of profound degeneration.

Dipsomaniacs are distinguished from other cases by the maniacal impulse to procure spirits, which at the time is an irresistible mania, filling every impulse and thought of the mind. In periodical cases it begins after a certain distinct interval, and grows rapidly up to a certain point of intensity, then dies away abruptly. In irregular dipsomaniacs it appears and disappears with the greatest irregularity, but is marked by the same maniacal tendency and impetuosity.

These cases differ from the inebriate in the intense longing for alcohol, and nothing else; while the inebriate suffers from a form of psychical pain and agony that calls for relief from any source, no mattter what: anything to quiet the irritable, agitated nerve-centres. The dipsomaniacs are more clearly insane, and seem to have crossed the border-line of sanity; while the inebriate crosses and recrosses it with confusing uncertainty. The form of injury from which these cases began is of interest, and suggestive of the importance of further studies in this field.

Of the 16 cases of periodical dipsomaniacs, the injuries were as follows:

2 cases had lacerated wounds of the head, and fracture of the skull.

7 cases of concussion from falls and blows on the head.

1 gunshot wound of the face.

1 gunshot wound of shoulder.

2 severe lacerated wounds of the hand and arms.

1 of fracture of the femur.

2 crushed foot and leg.

Of the 10 cases of irregular dipsomania, the following appeared:

3 cases of blows on the head and concussion.

2 of wounds of the face.

1 shell wound of the femur.

1 gunshot wound of the knee-joint.

1 blow on the abdomen followed by peritonitis.

2 severe wounds of the extremities.

The injuries of the remaining cases were distributed as follows:

2 fractures of the bones of the head.

18 cases of blows on the head and concussion.

10 fractures of different bones with contusions and lacerations.

5 cases followed extensive flesh wounds from burns and injuries.

3 blows on the abdomen, with peritonitis.

3 from hemorrhage, coming from injury of the artery.

1 followed the successful operation of removal of stone from the bladder.

9 cases came from general injuries of the extremities.

I have examined the dipsomaniacs separately, because all experience so far seems to indicate that dipsomania follows more often from injuries than any other cause. In the case of the inebriate, the injury may be only one of many and complex causes, at present largely unknown. The history of these cases pointed out clearly the beginning of inebriety, or the excessive use of alcohol from the time of injury, or immediately after, so that the connection could not be mistaken. In all probability these injuries were severe, and attended with mental shock and profound exhaustion and constitutional changes at the time, although the history on this point is not accurate. *A study of the influence of heredity in these cases was of great interest.*

In twenty-six instances inebriate ancestors were traceable in both the parents and grandparents. The most frequent histories were those of inebriate fathers and grandfathers on the mother's side. In eighteen cases insanity, epilepsy, and hysteria were marked in the ancestors of two generations. In ten cases phthisis, rheumatism, and a history of general degeneration were noted in the parents. In the remaining cases no special heredity was marked, and in several instances the parents were of a very high order of intellect. In a number of cases the parents were evidently overworked and generally exhausted, and living lives of great irregularity. In twenty cases the fathers were brain-workers, and in ten instances they were men of leisure and idlers. In one case the grandfather and father began to drink at forty, and died from excesses a few years after. The son was temperate up to thirty-nine, when he began to drink, following concussion of the brain. In another family nearly all the male members had died of consumption at about forty-two years of age. The last member fractured his leg at forty, and drank to great excess during convalescence, and for five years after, until admitted to the asylum.

In another case, in which consumption had been prominent in every member, one of the family had a gunshot wound of the jaw, and became an inebriate immediately after. Six years later he spent four months in an asylum, recovered, and consumption and death followed soon after his discharge. These and other facts show that heredity was a large factor in the causation.

Another *inquiry as to habits of these cases previous to the injury and drinking*, brought out the following facts:

In thirty-one of these cases there was a history of moderate and occasional use of alcohol before the injury. It was clear in most of these cases that no marked excessive use of spirits had preceded the

injury, and that the inebriety after was unusual and unaccountable. In twenty-one cases total abstinence from all spirits was claimed up to the outbreak of inebriety.

In the other cases the history bearing on this point was not clear, but at all events the inebriety following was distinct, and each one claimed that it began at a certain time dating from the injury. From a *grouping of facts bearing on the physical condition of these cases at the time of injury*, over half of them were evidently suffering from anæmia, exhaustion, and general debility at the date of injury. For instance, four were business men with great care and responsibility. Seven were overworked professional men, and many others were leading lives of much physical irregularity, and general neglect of all natural, healthy living.

It was clear from this that heredity, moderate drinking, general anæmia, and exhaustion, were very powerful factors in the causation. They had literally opened the door and prepared the ground for the development of inebriety or other neurosis. The injury was merely the explosion of a long train of causes that had been gathering in the past. The *progress of these cases* was more rapid, and the action of alcohol more profound. In most cases the toxic symptoms were prominent, the delirium and paralysis longer in duration, and all the phenomena more intense and active. The sudden onset of inebriety is always an indication of grave disturbance of the brain-centres, and the action of alcohol on these centres is soon followed by many indistinct forms of general paralysis. Psychical delirium and melancholy, with various complex physical and mental symptoms, merging into acute disease of different organs, appear with more or less regularity.

Cases which have no preparation of heredity, moderate drinking, or exhaustion, are less prominent, and follow a line more or less irregular and uncertain. The prognosis is better in these cases than in the other, and the sudden appearance of inebriety after some severe shock to the body indicates temporary failure of some central ganglion, which may recover after a time. The treatment varies with the case, but is all summed up in brain rest in circumstances the most favorable to build up and strengthen all parts of the body. This can only be successfully carried out in exact surroundings where all the functions and activities of life can be regulated and controlled. An asylum or hospital with every appliance of surroundings and service to this end is essential, and the time of treatment lengthened out to years will always give the best results.

An outline history of some of these cases will more clearly bring out the facts, and aid to further study.

It will be understood that all cases are not so distinct; that many present halts and obscure changes which, studied alone, are both vague and confusing, but, when seen higher up and collectively, are found to follow a distinct line from stage to stage.

They all correspond in beginning after some profound injury to the head or body. The following is a typical case of inebriety springing from traumatism direct.

A., merchant, thirty-four years of age; had always been a total abstainer; a man of position, family, and wealth. No heredity could be ascertained. Received a fracture of the skull from a falling box; was unconscious for a time, then recovered after a few weeks' rest and quiet in bed. No spirits were given, or suggestion of their use or value made, and yet suddenly he procured a quantity of brandy and drank to intoxication. He gave as the only reason that he wanted it, and must have it or die. In a short time periodical dipsomania appeared, and after three years of great excesses he came to the asylum. He recovered after four months' residence, but relapsed within a year, and died of cerebral hemorrhage. A state of abject helplessness, and failure to realize his condition, was prominent from the first.

Case II. was a bank clerk, forty years of age, strong, temperate, and a total abstainer. No heredity in the family. Was knocked down by a burglar and gagged, remaining unconscious for several hours. He suffered from a low fever for two weeks, then recovered, but brought home large quantities of spirits and drank to intoxication at night. He gave no reason for this conduct, but continued to drink every night, then developed into a dipsomaniac, and drank to great excess at times at night for five years. He then was admitted to the asylum, and finally disappeared after three months' residence. The opinion of his friends is that he relapsed and committed suicide.

Cases III. and IV. illustrate inebriety coming from injury, with a marked heredity.

B., a travelling salesman, thirty-four years of age, temperate, and hard-working. Father an inebriate, and mother died of consumption. Was a total abstainer from principle. Fractured his femur, and was laid up for four months. The next day after returning to work, he drank to great excess, and was a pronounced inebriate for many years. After two months' treatment he engaged in farming in the far west, and died a few months after from pneumonia.

C., a machinist, forty-eight years of age. A total abstainer, and a man of character and position. Father died of delirium tremens, and grandfather a periodical drunkard. Had his hand jammed so badly that amputation was necessary. He was confined to his room for three months, and all unexpectedly drank alcohol to intoxication. He became a periodical inebriate, and after some years of great excess was sent to an asylum, and recovered. Two years after he relapsed and is now in an insane asylum.

In the following cases a period of moderate drinking preceded the injury and inebriety:

D., a farmer, with no heredity of insanity or inebriety. Forty-two years of age, and well. Had drank spirits occasionally, but never to excess, using it only on special occasions, and with friends. He was thrown from a wagon, striking on his head, and suffered from concussion. Almost immediately he drank to great excess, and continued for two years, using it on every time and occasion. After an attack of delirium tremens he was brought to the asylum, but ran away in a few days, and finally died some months later from general excesses.

E., a lawyer and politician, was a moderate and occasional drinker, never using spirits to excess

and prided himself on his ability to drink always in moderation. He was thirty-nine years old, and in apparent health, when he received a severe blow on the abdomen followed by peritonitis. After recovery he became a steady inebriate, drinking spirits to intoxication every day. A few weeks' asylum treatment was followed by relapse, and his final disappearance in the far west as a chronic case.

These cases are distinct and unmistakable in their origin, but not unfrequently cases appear in which a history of moderate drinking preceded the injury, and excessive use of spirits or inebriety followed one, two, or three months after.

When such cases are studied, it will be found that some entailment of the injury, or symptom of impaired health and vigor, has remained over from the injury, and finally, from some unknown causes, developed into inebriety; very much in the same way that insanity or epilepsy appears long after some head or body injury has been sustained, and can be traced to it. Many very important questions gather about this subject, which cannot be answered at present, until some general study of a large number of cases is made.

The following conclusions may be accepted as representing the facts so far established on this subject:

1. Inebriety takes its origin directly from traumatism, particularly head injuries, in a certain percentage of cases.

2. Such cases are prominent in the sudden outburst of the drink-craving, its precipitate character and intensity passing into chronic conditions at once.

3. Complex psychical and physical phenomena, pointing to a general profound state of degeneration of the brain and nerve-centres, are present in nearly all cases.

4. The progress of these cases is generally uniform and along a certain definite line, with but few changes or variations.

5. In the history, heredity, moderate drinking, and habits of irregularity are common factors preparing the way for the final developing of inebriety, growing out of the injury to the system.

6. The prognosis is always grave and the treatment of little use, unless it is adapted to each case and extends over a sufficiently long time to warrant a full restoration.

7. The pathology and psychology are unknown, but practically the surgeon should remember that a certain number of his cases who inherit some inebriate or insane neurosis, or are moderate users of spirits, are likely to develop inebriety from the slightest causes. Hence alcohol should be withheld as a medicine at this time.

LACERATION OF THE CERVIX UTERI DURING LABOR.

By JOHN FERGUSON, B.A., M.B. Univ. Tor.; L.R.C.P. Edin.; L.F.P.S. Glasgow.

DEMONSTRATOR OF ANATOMY IN THE TORONTO SCHOOL OF MEDICINE, TORONTO, CANADA.

This important question has received a good share of my time for several years. As a student and practitioner both in this country and in Britain, I have taken every care to gather information bearing upon it. The results of this work I shall now lay before the profession; and, in doing so, must express the hope that others, who have better facilities for the same line of research, shall avail themselves of their privileges, and make known their conclusions in due season.

In coming to any fixed opinion on a question like the one now under consideration, many circumstances require to be carefully weighed, and unless a due share of attention be given to each of these our efforts may not only be useless, but positively misleading and hurtful to the cause which it is intended they should further.

To begin with, all our attention ought not to be directed to the case of laceration of the cervix, as it occurs in the human female. The comparative study of the question will throw much light upon our path, and enable us to avoid, on the one hand, many dangerous errors; and, on the other, to arrive at not a few valuable truths. Then we must assign a proper share of attention to all the circumstances related to labor, as conducted under widely different conditions in the same race or class of persons; and again, as it occurs in different races and in different climates, and in these again as it is affected by very varying customs or fashions during the progress of parturition.

In the first place, I shall glance into the comparative side of the question. These observations were made on ewes, bitches, cats, cows, mares, and sows. In the case of the ewes, fifteen were examined, all having had lambs on one or more occasions. The cervix in all of these was healthy and normal, with one exception, in which there was a very slight laceration. There was not the slightest evidence, however, that this laceration had given rise to any diseased condition of the cervical or uterine tissue. Nineteen bitches have been examined. Some of these have had pups a number of times. In no case could any laceration be found. The cervices were quite healthy and firm. The uterus and cervix of thirty-five cats, have, so far, been carefully seen. These animals were all, I believe, multiparous. In only one was there the least evidence of tearing; and in this case it was so very slight as scarcely to deserve any mention, further than to show the results of the search. Two hundred uteri from cows have been subjected to scrutiny. These, like those of the sheep, were obtained from slaughter-houses. Of these two hundred, three showed some laceration, though not to any great extent, and one very slight fissuring. The tissue of the cervix in these four seemed, however, quite healthy, and contradicted the notion that a laceration necessarily leads to any unhealthy state of the part involved. It is almost unnecessary to state that all these cows had given birth to calves. Five samples have been examined from mares. In one there was laceration. This mare had had six foals. The others had one, two, four, and nine respectively. Although there was fissuring in these four, the injury was extremely slight. Thirteen sows' uteri have been examined, and with negative results in all cases.

Thus far, two hundred and eighty-seven animals

have been examined, yielding seven cases in which there was more or less damage done to the cervix during the act of parturition. In none of these seven did there appear to be any evil results from the lacerations such as they were, judging from the condition of the cervical tissue.

Now, turning to the human female, much real information can be gained by studying examples of cervical laceration as they occur under different circumstances. The first group I shall refer to is that in which laceration took place, and in which the labor was hurried by medicinal agents. In this group I can place altogether twelve primiparous women. Three were attended by physicians, and nine by midwives. From the statements made by these twelve, there is no doubt that ergot had been given to hasten labor in the early stage. These persons state that something was given to them which caused severe and steady pains, and that, too, before they had been long in labor; in some cases, before any escape of water or the appearance of a "show." Now, of these twelve, there is unmistakable evidence of laceration of the cervix in ten of them. This is surely a fearfully large percentage! Had these women been left alone, with no other help than that required to cut the cord and take the child out of the way, things would have gone much better with them.

The next group contains twenty-one cases. They are all examples of forceps-delivery, and are also primiparæ. Five of these I had the opportunity of examining while in Britain. Four came into my hands after coming to Toronto, from various parts of Britain. All of these said that forceps had been used; and in eight there was well-marked laceration. Eight were attended in this country in different parts, yielding six examples of laceration. In four cases, which occurred in my own practice, in which forceps had to be used, there were lacerations in three, as shown by examination made some time afterwards.

Here, then, we have twenty-one cases of first births aided by forceps, and presenting seventeen examples of well-marked laceration. This is also a pretty high percentage. Now, it would be unfair to say that this was entirely due to the mere fact that the forceps were used; much of the real cause, no doubt, could be found in the conditions demanding their use. In my own four cases of primiparæ, followed by lacerations, the forceps were a necessity. Still, it cannot be denied that their use does tend to the production of this misfortune; and every caution should therefore be used always in their employment.

The next group of persons, twenty-nine in number, had been confined only once. In these there was no evidence that any urging drug had been used, nor had the forceps been employed, in the cases that had been attended by other physicians, eleven in all. In the remaining eighteen, delivered by me, the progress of the labors was left entirely to nature. In the eleven cases attended by others, there was no laceration worthy of the name; while in the eighteen attended by me, there was one case of slight laceration, which, however, gave rise to no disturbance, and was left, as a consequence, untreated.

Thus it will be seen that of twelve cases urged on by ergot, there were ten examples of laceration; and of twenty cases assisted by the forceps, there were seventeen branded with this mark. On the other hand, twenty-nine labors left to nature, gave only one lacerated cervix.

When we take into account the statements now made regarding the lower animals and the human female, it seems to me no difficult matter to draw the inference that the attendant should learn to refrain from useless interference with his midwifery cases; and, when he must interfere, he should be able to take his bearings well, and then proceed accordingly. It would be hard to conceive of any more dangerous belief than that the forceps must always be applied simply to save our time, or an hour or two of what may be called natural suffering on the part of our patient, needed to complete a normal labor. If the physician be so crowded with engagements that he cannot spare the requisite time, then he is in duty bound to humanity to relinquish some of his work. If he has not the heart and sympathy in his calling which will induce him to give to his patients all the advantages that medical science puts in his hands, then the sooner he abandons the profession of the healing art, the better will it be for his fellow-beings, and ultimately for his own conscience.

In conclusion, I would add, that it is not good philosophy to preach and practise the doctrine of shortening the sufferings in labor by the too ready use of forceps, at the risk of causing an injury that may give rise to life-long misery, or necessitate an operation attended by more real suffering and distress to the unfortunate woman, than the few labor pains that would have been required to complete the act of childbirth.

HOSPITAL NOTES.

TERRACE BANK HOSPITAL FOR WOMEN, PITTSBURG, PA.

Service of Dr. R. S. Sutton.

(Reported by Wm. L. Stone, M.D.)

MR. LAWSON TAIT'S OPERATION FOR SUPPURATING HÆMATOCELE.

Mrs. Thomas S., an English woman aged thirty-two, was sent to Dr. Sutton about the first of June, 1884, on account of a painful enlargement of the lower portion of the abdomen. The pelvis was full, the uterus misplaced; the patient was thin, anæmic, and bore a haggard countenance. After examination, the mass, in which fluctuation was evident, was diagnosticated an abscess. As there was no bed empty in the hospital at the time, she was sent home with a letter to her physician, requesting him to tap the collection without delay. This was done by Dr. J. Q. Robinson, of West Newton, on the following day, and a very large quantity of pus was evacuated. For two weeks the patient improved in every way; by the end of three weeks the sac was full again, and she was suffering pain. Again she was

sent back to Dr. Sutton, who received her into his private hospital on June 21st, and performed Mr. Tait's operation on June 24th in the presence of Dr. Robinson, of West Newton, Pa., and Dr. Knox, of McKeesport, Pa.

An incision two inches long was made through the abdominal wall, and all bleeding was so effectually controlled that no blood entered the cavity of the abdomen. The peritoneum at the edges of the abdominal wound was then closely stitched, with antiseptic silk, on to the dome of the abscess sac lying in full view. The sutures were cut short, to be left. An aspirator trocar was introduced through that portion of the sac wall left exposed, and pus was immediately found, but it was so thick that but little could be withdrawn. The sac was now laid open and nearly a quart of pus and blood-clots was removed from its interior. The wound was cleansed of all pus and blood and well dusted with iodoform. A large glass drainage-tube was introduced to the bottom of the sac, and the wound was closed with silkworm-gut sutures above and below it. Each suture included the pus sac which was thus secured to the abdominal wound by a double row of sutures, viz., the row uniting the peritoneum to the peritoneum covering the sac and the row closing the abdominal wound, each suture also including the sac. Prior to the operation her temperature was 99°. Six hours after the operation her temperature fell to 98.4°, and never rose above normal afterwards. On the sixth day a smaller glass tube was substituted for the large one. On the eighth day this was removed and a small rubber tube inserted. This tube and the stitches uniting the abdominal wound were removed on the fourteenth day. She returned home on the twenty-second day after the operation apparently perfectly cured, and no further trouble has been reported.

The operation was in every way satisfactory, and Dr. Sutton remarked that Mr. Tait had, by giving us this operation, done much practical good for this class of cases.

MEDICAL PROGRESS.

Resection and Extirpation of the Astragalus.—Dr. Margary, of Turin, reports two cases in which he operated on the astragalus for club-foot.

The first case was that of a man, thirty years of age, who acquired a very pronounced pes equinus, with astragalo-tibial ankylosis, after an internal subastragaloid dislocation. Following the precepts of König, Margary resected a wedge which comprised the whole of the head, the greater part of the neck, and three-fourths of the body of the astragalus, as well as the external malleolus, and corrected the deformity at the same time. Three months afterwards, the patient was presented before the Académie de Médecine of Turin. The form of the foot was correct, and the foot itself as solid as could be desired.

The second case was that of a man, twenty-eight years of age, who had sustained a dislocation similar to that in the preceding case. He also had pes equinus, and walking was painful, though there was no ankylosis. Dr. Margary extirpated the artragalus piecemeal. Four months afterwards, the man walked easily and without a cane. The movements of the foot were quite natural.

Margary also refers to a case in which Dr. Raffa resected the head and neck of the astragalus for pes varus, due to an old luxation of the astragalus. The correction was perfect in this case also.—*Gaz. Hebdom. de Montpellier*, July 12, 1884.

Corrosive Sublimate and other Antiseptics in Ophthalmology.—Sattler has recently made some extensive experiments as to the value of different antiseptics, when used in infected animal tissues, and especially in the eye. For this purpose he used silk threads sterilized by heat and then placed in cultures of micrococci from the lachrymal sac or jequirity bacilli. These threads were then dried with care, so as to prevent the access of other substances, and then dipped, with their cultures, into different antiseptic fluids for a longer or shorter time, according to the time which the disinfecting fluids are usually kept in contact with the tissues. Afterwards, the threads were again put in the culture chambers and observed.

His experiments showed that chlorine water by far exceeded all other antiseptics, and rendered every spore incapable of development in one minute. Next in value to chlorine water was a solution of corrosive sublimate, 0.5 to 1 per 1000. Three minutes longer were necessary for solutions of 1 to 5000. Third in the list were resorcin and hydroquinone in 3 per cent. solutions. Very favorable results were also obtained with concentrated watery solutions of salicylic acid, and almost the same results were obtained with 2 or 2.05 per cent. solutions of carbolic acid. Boracic acid was shown to be extremely weak, even in concentrated solutions; thymol (1 : 1000) was much better in concentrated watery solution. Hydrogen peroxide, iodoform, and absolute alcohol gave also comparatively slight results. When spores of splenic fever were used, chlorine water and corrosive sublimate gave favorable, and the other substances unfavorable, results.

Sattler says that in severe corneal ulcer the best antiseptic is the incandescent iron, most conveniently used in the form of the galvano-cautery. Severe hypopyon is then quickly absorbed, and painful ciliary neuralgia disappears in a very short time.—*Centralbl. f. d. med. Wissensch.*, July 19, 1884.

Hæmatocele in a Cyst of the Cord, with Abdominal Prolongation.—Dr. Routier, Chief of the Surgical Clinic at La Charité, reports the case of a man, æt. 35 years, who, four years previously, had noticed that his scrotum had swollen on the left side, without appreciable cause. This swelling grew to a large size in a few weeks, and extended up into the groin. He had never had gonorrhœa, and had never had an injury of that region. Three years after its first appearance the tumor was punctured and iodine injected. He stated that on puncture being made *two quarts* of fluid resembling urine were drawn off. He seemed to be cured by this operation, but three months afterwards the swelling reappeared, and again assumed large proportions. The left side of the scrotum was now as large as the two fists, was rounded, elongated, and regular, and the tumor extended up into the inguinal region. At the lower part was a sort of rounded lump, which seemed added to the whole mass.

The skin over the scrotum was supple, elastic, and

glided over the deeper parts in a normal manner. The tumor was soft on palpation, and fluctuation was made out in every part. A cough-impulse was easily discerned in the scrotal part of the tumor, and this could be gradually followed up to about two inches below the umbilicus. The corresponding iliac fossa was not involved; it was certain, therefore, that the pouch containing the liquid turned toward the median line, after passing through the inguinal canal. There was absolute dulness wherever there was fluctuation, and there was no transparency of the scrotum by transmitted light. The tumor was irreducible, and the patient had never had hernia. The testicle was clearly defined in the lower part of the tumor, and appeared to be separated from the remainder of the tumor. This position of the testicle seemed rather to indicate an enormous cyst of the cord, than an ordinary vaginal hydrocele. The diagnosis was settled, however, by an operation which disclosed a hæmatocele in a cyst of the cord.

The operation was performed in the following manner: After an exploratory puncture, which confirmed the diagnosis of hæmatocele, an incision was made into the scrotum and sac, which brought away about a quart of a thick, grumous, chocolate-colored liquid. The cavity was then found to be lined with a thickened false membrane, which was easily removed with the finger-nail and the curette. Anatomically, the sac was divisible into three parts: 1. The scrotal portion, which was easily removed. The testicle appeared to be in a perfectly healthy condition. 2. The inguinal portion, which was also easily removed. 3. The abdominal portion, into which the finger could be forced far enough to distinguish two prolongations; one pointing toward the umbilicus, the depth of which could only be reached with difficulty; the other seemed to descend into the pelvis, and its termination could not be reached. So far as possible, the internal face of this large cavity was scraped and cleaned with mounted sponges, with which the pouch was thoroughly scoured.

When the cavity had been cleared of false membrane, a sponge soaked with solution of zinc chloride was carried in; this being done, the walls of the cyst, which were at least one thirty-fifth of an inch in thickness, were closely sutured with catgut, the interrupted suture being used. Two large drainage-tubes were then placed in the abdominal portion of the pouch, and two others in the scrotum, and the wound closed with silver sutures, after which a Lister dressing was applied. The wound was completely cicatrized in a month and a half.

Cases of hæmatocele of cysts of the cord are very rare. Duplay mentions two cases, of Huguier and J. Rochard. Knipe (*Lancet*, 1880, vol. ii. p. 300) reports a case exactly similar to the one here recorded. Gray (*Lancet*, Sept. 1883) reports a case of extensive hæmatocele of the scrotum, extending up into the abdomen, but the situation of the testicles is not mentioned. He punctured and injected carbolic solutions, which caused suppuration. He then made a large opening, resected the exuberant portion of the scrotum, and the patient recovered. Bérand (*Archives Méd.*, 4th ser., vol. xxv.) reports two cases operated on by Velpeau and Cabaret. Curling reports three cases of encysted hæmatocele of the cord as very rare occurrences. In 1876, *à propos* to a communication from M. Ollier regarding a case of hæmatocele of the epididymis, Professor Guyon said that he had had three cases of cyst of the epididymis transformed into hæmatocele. In each case the cyst was as large as the fist. The testicle was always healthy, and was always on the outside of the cyst.—*Progrès Méd.*, July 5, 1884.

A Sea Atmosphere for the Sick-room.—Dr. B. Ward Richardson says that the solution to be used and diffused as a spray consists of solution of peroxide of hydrogen (10 volumes strength), containing 1 per cent. of ozonic ether, iodine to saturation, and 2.5 per cent. of sea salt. The solution placed in a steam or hand-spray diffuser can be distributed in the finest spray in the sick-room at the rate of two fluidounces in a quarter of an hour. It communicates a pleasant sea odor, and is the best purifier of the air of the sick-room he has ever used. It is a powerful disinfectant as well as deodorizer, acting briskly on ozonized test solutions and papers. Mr. Carl R. Schomberg has recently invented a large spray-producer, which will diffuse the artificial sea air through a hospital ward.—*The Asclepiad*, July, 1884.

Internal Strangulation caused by Extrauterine Pregnancy.—M. Notta reports a case of this kind, operated upon by M. Bouilly. The woman was forty years old; had for several days suffered from vomiting of bilious and fecal matter, and had distinctive symptoms of intestinal occlusion. The symptoms were so grave that M. Bouilly at once decided to practise laparotomy.

A large tumor had been recognized in the right flank, the first manifestations of which had appeared seven years before. The abdomen was opened, and the tumor found to be a fœtal cyst. The fœtus and its envelopes were contained in a thickened fibrous pouch, formed by the remains of old peritoneal false membranes. The fœtal cyst was easily removed, and M. Bouilly found that the intestine traversing the peritoneum at the upper and posterior part of this capsule was strangulated. The adhesions were loosened, and the wound closed. The patient died of collapse on the next day.—*Revue Méd. Franç. et Étrang.*, July 26, 1884.

Resection of the Pylorus for Cancer.—At a meeting of the Medical Society of St. Petersburg, Dr. Baikoff (*Vratch*, 1883, No. 8) reported the case of a woman, aged thirty-eight, who for three years had suffered from heartburn, eructations, and constant vomiting after every meal, and, of late, had become extremely cachectic and emaciated. The stomach was found much distended. In the situation of the pylorus there could be felt a hard, nodulated, movable tumor. The operation was performed under chloroform and the carbolic spray, and lasted four and a half hours. A transverse incision, 12 cm. ($4\frac{3}{4}$ inches) in length, being made, the peritoneum was united with the skin. The tumor, 11 cm. ($4\frac{2}{5}$ inches) in length, 7 and 8 cm. ($2\frac{4}{5}$ and $3\frac{1}{5}$ inches) in breadth, occupied the pylorus and adjacent parts of the stomach and duodenum. The neighboring glands were slightly enlarged, but not infiltrated. The tumor was isolated and gradually separated by scissors, first from the small curvature and then from the duodenum, the wound in the stomach being closed step by step with the removal of the new growth. The

remaining part of the latter was cut away after the duodenum had been sewn up to the stomach. About a hundred vessels were tied with catgut, and about eighty catgut sutures (Nos. 0 and 1) were used for closing the wound in the stomach and duodenum. The abdominal incision was treated after Lister's plan. The pulse after the operation was small and intermittent, but the patient soon recovered under the influence of a hypodermatic injection of musk, camphor, and ether. There was no fever up the third day, when a slight elevation of temperature occurred. On the fifth day the dressing was changed, several sutures being removed, and the patient, who had been up to that date fed through the rectum, began to take milk. On the seventh day, however, she died, after complaining of pressure and pain in the epigastric region. The post-mortem examination showed that the stomach was distended with fluid, though the exit was entirely free, since the contents of the stomach passed into the bowel when the body was turned on its right side. The gastro-duodenal wound was firmly closed with adherent inflammation. The author thinks that the patient died from exhaustion and a paralytic state of the stomach. The tumor was scirrhus, with partial transformation into medullary cancer.

In the same number of the same journal, Dr. N. A. Veliaminoff details the case of an extremely emaciated and nervous woman, aged forty-two, who presented all symptoms of a movable cancerous tumor of the pylorus, and in whom Professor K. K. Reyher had excised the latter. The length of the transverse abdominal incision was seven centimetres. The tumor was removed as a whole, the gastric wound being closed by double (*i. e.* both by mucous and serous) sutures. The operation was conducted without spray, and lasted about four hours. By the end of the second hour of the operation, collapse appeared, and eight hours after the resection the patient died from exhaustion.—*London Med. Record*, July, 1884.

The Infectious Genesis of Relapse of Tubercular Granular Degeneration after Operations on Tuberculous Glands, Bones, and Joints.—M. Wiskemann (*Archiv f. klin. Chir.*, Bd. xxx. S. 341) has treated, between July, 1879, and January, 1882, at his private hospital in Illzack, eighty children and young persons for tuberculous diseases of the lymphatic glands, bones, and joints. In no case was there any accidental wound complication. Only three patients died, and two of them of tubercular meningitis. Of the different ways in which tuberculous relapse may occur, Wiskemann lays special stress on what he terms "latent infection." He recommends crystallized iodoform more as a prophylactic in clean wounds than as a dressing for granulating surfaces.—*Centralbl. f. d. med. Wissensch.*, July 26, 1884.

Extirpation of the Larynx.—Mr. Thomas Jones removed, at the Manchester Royal Infirmary, on April 26th, the whole larynx, on account of epithelioma, from a man aged forty-four years

A vertical incision was made in the median line of the neck, reaching from the hyoid bone above to the thyroid isthmus below. The structures were carefully separated from the front of the thyroid cartilage, which was then divided and the two halves separated. The interior of the larynx thus brought into view was found to be almost completely filled with a new growth. The mass reached upwards to the epiglottis and downwards as far as, and to a certain extent into, the trachea. The extent of the growth made it evident that nothing short of complete extirpation would be of any avail. In order to do this, more room was required, and it was obtained by prolonging the incision downwards to the sternum, then dividing several more rings of the trachea so as to push the tracheotomy tube further down. This being done, the soft parts were now dissected off the sides of the thyroid cartilage and its attachment to the cricoid severed. The left half of the thyroid was then removed, its remaining attachments being divided with scissors. The right half, including the epiglottis, was treated in the same way. The laryngo-pharyngeal septum was found to be so extensively infiltrated that it was impossible to separate the larynx from the pharynx, so the whole of the anterior and lateral walls of the latter were taken away, only a portion (about an inch wide) of the posterior wall being left. This was subsequently divided and sutured to the margins of the skin incision. The cricoid cartilage, together with the first ring of the trachea, was next excised. The upper end of the trachea, was fixed to the skin by a carbolized silk suture on each side. Above the points at which the œsophagus was attached to the skin there was a large cavity which communicated with the mouth. It was washed out with a solution of chloride of zinc (forty grains to the ounce), and afterwards plugged with iodoform gauze. The patient left the Infirmary on June 14th, wearing one of Foulis's tubes, and taking all nourishment by the mouth.—*Lancet*, August 2, 1884.

Pulmonary Gangrene.—The sputa of such disagreeable odor expectorated by persons who have pulmonary gangrene always contain elastic fibres in large quantity. It would seem, then, that the elastic fibres of the lung, are dissociated and partly destroyed by a sort of special *ferment*, and various attempts have been made to prove the existence of this ferment. Glycerine has been added to the sputa from a gangrenous lung, and the mass filtered. For a comparative experiment, putrid liquids of another kind, and sanious pus from the pulmonary cavities of persons dead of tuberculosis, are taken. The elastic tissue dissolves in the filtered gangrenous liquid in two days, whilst it remains intact in the putrid liquids for about five days.

For the gangrenous liquid, this solution is made in an alkaline medium. But if the elastic fibres are placed in a solution of pepsin, the latter must be acidified. With pancreatine, on the contrary, the elastic tissue is dissolved in a neutral medium. However this may be, there is a true solution by means of a gangrenous ferment, which acts as a gastric ferment on the elastic tissue, which is so resistant to chemical agents.

It appears that this gangrenous ferment dissolves the albumen of white of egg, and does not dissolve colloid substances. If, therefore, it be desired to stop the rapid liquefaction of the pulmonary tissue in cases of gangrene of the lung, or of acute tuberculosis, some substance must be found which will hinder the action of this ferment. From certain experiments, Filehne believes in the efficacy of thymol, turpentine, phenol,

salicylic acid, and sulphate of quinine. But as these substances only act when concentrated, he proposes to inject them directly into the pulmonary cavities through the thoracic walls; but he advises that experiments be first made on animals, in order to determine the exact effects caused by such procedures.—*Revue Méd. Franç. et Étrang.*, July 26, 1884.

TREATMENT OF SYCOSIS.—The *Wiener med. Blätter*, of April 24, contains an article by DR. VON HEBRA, on a new treatment of sycosis. Being dissatisfied with the customary maceration of the skin by means of diachylon ointment, he sought, some years ago, to discover some means by which this might be prevented. He now employs almost invariably the following plan of treatment. Any hair which may be left on the parts affected is cut as close as possible with scissors, and some emollient ointment applied for twenty-four hours, care being taken that it does not contain lead, which would form a compound with the sulphur to be subsequently employed. The crusts being by this time broken down, the part is shaved, by which means the tops of the pustules are removed and their contents evacuated. The whole of the affected surface of the face is then covered with a modification of Wilkinson's ointment, included in the Hungarian pharmacopœia under the name of "Unguentum contra scabiem," which is covered with a piece of flannel, and secured by a calico bandage. This dressing is changed every twenty-four hours, when the contents of each pustule are pressed out, and the hair which is usually found in the centre removed. When all the pustules have disappeared, the redness and scurf are removed by the application of an ointment containing one part of zinc to three of vaseline, and the cure is complete, in some cases within a few days. Several cases are cited in illustration.—*London Med. Record*, July, 1884.

QUININE IN SUPPOSITORIES.—R. PICK recommends the use of quinine in the form of suppositories, by which better effects may sometimes be obtained. For children, gr. xv to xxij of muriate of quinine may be made up with gr. xxx of coca butter, and some simple cerate. He recommends that an enemata be given one hour before the introduction of the suppository, and, further, that, in very restless children, the suppository may be introduced during sleep.—*Centralbl. f. d. med. Wissensch.*, July 26, 1884.

OPERATION FOR ABSENCE OF LOWER END OF RECTUM, AND PASSAGE OF FECES THROUGH PENIS.—DR. FRANCIS J. SHEPHERD, of Montreal, reports the case of a child, three days old, which had an imperforate anus, and passed its feces through the penis. It had a very slight fulness of the perineum, a well-marked median raphe, and a slight puckered depression at the site of the anus. He decided first to try and reach the bowel through the perineum. After placing the child under chloroform, he made a free incision in the median line, dissecting carefully backwards and upwards in the direction of the rectum, and frequently placing his finger in the wound to feel for fulness or fluctuation. He dissected in this way to a depth of fully two inches, when, discovering a fluctuating tumor, he punctured it with his knife, and was pleased to see large quantities of feces escaping through the wound. He then enlarged the puncture in the bowel, and without much difficulty drew it down to the external wound, and held it there by catgut stitches.

The child was seen seven months afterwards, and was in good health.—*Edinburgh Medical Journal*, August, 1884.

GASTROSTOMY.—DR. N. A. VELIAMINOFF, of Prof. Reyher's clinic, reports (*Meditz Obozrenie*, Fasc. 5, 1884) the case of a man, æt. fifty years, who suffered from cancer in the middle third of the gullet, and in whom he did gastrostomy (in two stages, with four days' interval). The patient got up on the third day after the operation, and four and a half weeks later he was shown to a meeting of the St. Petersburg Medical Society. Two months after gastrostomy he returned to his occupation. The patient died from cancerous perforation of a bronchus in the eighth month after the operation.—*London Med. Record*, July, 1884.

RESECTION OF THE LINGUAL NERVE FOR NEURALGIA.—W. J. KUSMIN reports (*Letopis Chirurg. Obschtschest.*, v. Moscow, No. 1, 1884) the case of a man, æt. 62 years, who for three years had had neuralgia of the third branch of the trigeminus, in the left half of the mouth, the tongue, in the region of the mental foramen, and in the zygomatico-temporal region. Section of the mental nerve and of the auriculo-temporal branch of the trigeminus caused only temporary abatement of the trouble. One year ago, the inferior alveolar branch was resected at its entrance into the lower jaw; this gave only temporary relief. Finding that pressure on the lingual nerve caused pain, Kusmin resected it at the border of the tongue, behind the sublingual gland. The pain ceased entirely in three days, and the patient has not felt it now for six months.—*Centralbl. f. Chir.*, July 26, 1884.

EXTIRPATION OF THE LUNGS.—BIONDI reports the results of numerous experiments made on sheep, dogs, and cats. Partial extirpation, and amongst others that of both apices, were all followed by cure; total extirpation of one lung was successful in more than fifty per cent. of the cases, and several deaths seem to have been due more to some imperfection in the antiseptic dressing than to the operation itself.—*London Med. Record*, July, 1884.

MASKING THE TASTE OF IODIDE OF POTASSIUM.—MR. GÉRARD LAGUE says that syrup of currants completely disguises the taste of iodide of potassium; and persons who cannot take this drug on account of its disagreeable taste may use it by adding that syrup.—*Revue Méd. Franç. et Étrang.*, July 26, 1884.

FORMULÆ FOR RESORCINE.—SCHMIDT gives the following as a useful formulæ for the administration of resorcine. For vaginal injections: Resorcine, gr. xv–xxx; water, f℥ij. For hypodermatic injections: Resorcine, ℈iv–℥v; water, f℥iij. For topical application: Resorcine, ℈iv–℥ijss; glycerine (neutral) or vaseline, ℥j. For internal administration: Resorcine, ℥ss–℥j; simple syrup, f℥ijss; aromatic water, f℥iij. The last to be taken in doses of one teaspoonful every two hours.—*Revue Méd. Franç. et Étrang.*, July 26, 1884.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, AUGUST 23, 1884.

THE COPENHAGEN CONGRESS has adjourned, and has left the pleasantest of recollections in the memory of all who participated in its proceedings. Sufficient time has not yet elapsed for us to estimate accurately the scientific outcome of the meeting, but our cabled reports justify the opinion that it was worthy of the occasion, and of the distinguished men of our profession who had gathered in the Danish capital to take part in its deliberations.

As we foreshadowed last week, we now have the pleasure to congratulate the American profession on the acceptance of the invitation to hold the next session in Washington. In extending that invitation the profession assumed a weighty responsibility, and in its discharge it will be found no easy task to equal the success which our Danish colleagues have just achieved, and of which they have good reason to be proud.

TUBERCULOSIS OF THE MEDIASTINAL GLANDS AND PURULENT PERICARDITIS.

IN the earlier days of pathology a large proportion of the cases of pericarditis were looked upon as primary or spontaneous. As investigations into the anatomy of this inflammatory disease became more extensive and accurate, it grew evident that cases of this kind are in fact of rare occurrence. This is not only true in the sense that many cases of pericarditis are merely the local expression of some form of general disease, but also for the reason that in numerous instances cases apparently idiopathic have been found upon exact anatomical investigation to be secondary to local inflammatory processes, often of such a kind as readily to escape observation, in the immediate neighborhood of the pericardium.

In addition to the long-recognized connection between inflammatory processes of the pleuræ and of the endocardium and pericarditis, attention has been more and more fixed upon the structures of the mediastinum and especially upon the intrathoracic lymphatic glands. Zenker, in his investigations upon the influence of chronic inflammatory processes in the mediastinum upon the formation of œsophageal diverticulæ, years ago directed attention to the occurrence of perforative pericarditis in these conditions, and reported among fifty-four cases of traction-diverticula of the œsophagus from disease of the lymphatic glands, nine cases of complete and one of partial pericardial adhesion. In 1879 the same observer again insisted upon the part played by inflammation of the structures of the posterior mediastinum in the pathogenesis of pericarditis, and emphatically asserted that the lymphatic glands of this region were commonly the overlooked source of the inflammation.

Barety, in 1874, found among 101 cases of disease of the thoracic glands 18 in which the pericardium was implicated, sometimes showing effusion, sometimes the lesions of past inflammation, from mere cloudiness to complete obliteration of the pericardial sac. In all these cases there was cheesy degeneration of the affected glands in various stages. In 11 cases of pericardial effusion, Barety found the fluid serous in 9, and sero-hemorrhagic in 2. Zahn reported, in 1878, an interesting case of *purulent* pericarditis caused by the double perforation of a knot of lymphatic glands into the œsophagus and pericardium. The softened glands occupied a position between the bifurcation of the trachea and the aorta, and the opening into the pericardium was situated at its upper posterior wall. The sac itself was filled with a great quantity of thick, purulent, but not ill-smelling, fluid. Eternost, in an elaborate study of the chronic affections of the tracheo-bronchial glands and their results, in 1879, reported several instances of perforation of the pericardium by the softening of melanotic glands, with more or less extensive soldering of the pericardial surfaces by pseudomembrane, which was in several cases pigmented.

In the light of the rapidly advancing knowledge of the relation which the lymphatic apparatus, and especially the lymphatic glands, bears to the organized causes of disease (microbes), these glands must be looked upon as most dangerous neighbors for the pericardium. Modern pathology, largely concerned as it is with the subject of tuberculosis, affords to-day no more important matter for investigation than tuberculosis of the lymphatic structures in all their relations.

Prior to the discovery of Koch, Weigert, in a series of communications collected in his work on tuberculosis of the veins, recognized the intrathoracic lymphatic glands as the starting-point of the tuberculous virus into the blood-stream, and derived from anatomical considerations much support for the doctrine of the infectious nature of the tubercular process. The final recognition of the parasitic character of this virus, so far from diminishing the importance of such anatomical studies, has, in fact, greatly increased it. The question of the mode of entrance of the tubercle bacilli into the various organs, as well as into the blood-stream, continues to be the subject of earnest discussion.

As regards tuberculous inflammation of the serous membranes, Weigert urged the view that it is almost without exception due to direct infection from neighboring organs by contiguity. Especially has this author insisted upon the secondary nature of those cases of tuberculous disease of the pericardium in which the extension of the affection from a tuberculous pleura could be excluded, and which, therefore, have appeared to be instances of "primary" tuberculosis derived from infection through the blood. In these very cases, the lymphatic glands of the thorax constitute a swarming depot for the organisms which infect the pericardium by contiguity, and, in truth, less the bronchial glands themselves than the little glands which lie on the anterior surface of the pericardium in the mediastinum, or which are situated at its summit, in the region of its attachment to the great vessels.

Dr. Alfred Kast (*Virchow's Archiv*, June 6, 1884) has recently reported a case of great interest as bearing upon this matter. A laboring man, aged fifty-three, died of exhaustion, with purulent pericardial effusion and serous effusion into both pleural sacs. Seventeen days before death, 36 ounces of thick pus had been aspirated from the pericardial sac. This fluid was filled with tubercle bacilli. At the post-mortem examination, there were found cheesy degeneration and central softening of the lymphatic glands of the neck, of the anterior and posterior mediastina, and of the roots of the lungs; perforation of a cheesy lymphatic gland into the pericardium; induration of the apices of the lungs; moderate chronic and miliary tuberculosis of both lungs; and double pleurisy, with compression of both lower lobes. The pericardium was free from tubercle. Kast calls attention to the composition of the aspirated fluid which, although laden with bacilli, did not present the appearances usual in effusions due to tubercular inflammation of serous membranes. He attaches to a bacillus-laden effusion, without tuberculosis of the inflamed serous membrane from which it is derived, a general diagnostic value, as indicating the perforation of the serosa by an adjacent softening tuberculous gland, or, in the case of the heart, by a softening solitary tuberculous mass in its muscular walls. He also regards the existence of bacilli in the pus of pleurisy as likewise indicating the perforation of the pleura by a softened peripheral cheesy mass.

The differential diagnosis between bacillus-containing, usually purulent, "perforation-exudations" and the serous or sero-hemorrhagic effusions without bacilli which accompany the miliary tuberculosis of serous membranes, and the serous and purulent inflammations which are excited by a neighboring inflammatory process, without perforation, will hereafter be attended by little difficulty.

Weigert has suggested that the tendency of the tuberculous matter to invade the entire organism through absorption from serous sacs is counteracted by another peculiarity of this virus, namely, its tendency to produce cheesy inflammation. By this process it rapidly blocks the lymph-channels leading away from the serous cavities, and in this manner, especially when there is a sudden eruption of bacilli in great numbers, prevents general tuberculosis.

SUTURES OF THE ABDOMEN.

Now that abdominal section is such a frequent operation, the question as to the method of using sutures is one of great practical importance, and a valuable paper which has recently appeared from the pen of Bako, of Budapest, on this subject is of timely interest. He points out that sutures badly applied are not without inconvenience, and may even produce hernia. But we have never seen a hernia after an ovariotomy unless the patient was up too soon, or supporting strips of adhesive plaster were neglected, or a bandage was laid aside too early. Nevertheless the accident may arise by the improper application of sutures.

Bako gives the following classification of sutures: First, those which include the abdominal walls and the peritoneum. This is the practice followed by almost all ovariotomists, and is not, as the author seems to indicate, peculiar to Spencer Wells; ovariotomists in America operating before Spencer Wells did, used the suture in this way. The second variety of abdominal suture is that which does not include the peritoneum: this method is followed by Olshausen and Kœberlè. The third variety is that in which two sets of sutures are employed, one for the peritoneum, and the other for the abdominal walls. The last plan is that practised by Kovacs. In it the peritoneal margins are carefully united by catgut sutures, and then the ordinary sutures are introduced so as to penetrate to the connective tissue immediately in front of the peritoneum, not including the latter. When superficial sutures are used, they should embrace the skin only, for, penetrating more deeply, they narrow the extent of the surfaces

brought together in the antero-posterior direction, lessening the size and consequently the firmness of the cicatrix.

The objection to the sutures which include the peritoneum with the abdominal walls is that they draw the peritoneum into the abdominal wound, and hence, when union has occurred, the line of adhesion is thinner than the rest of the abdominal wall, and is unable to resist the pressure of the abdominal viscera, and hernia results. In the second variety, the peritoneum not being included, its edges often fail to unite. Nevertheless we find that Kœberlé does not regard this failure of union as probable, and thinks it much better to have the edges of the peritoneum approximated beneath the sutures than to include them in the sutures.

Two objections to the exclusive sutures of the peritoneum may be urged: The operation is protracted, and wounds are multiplied. Such wounds as are made in carrying a catgut suture through the peritoneum are not of insignificant size, and moreover they are liable to tear, and thus a lacerated is added to a punctured wound.

THE VIRULENT AGENT OF PUERPERAL SEPTICÆMIA.

Some recent investigations by Arloing as to the virulent agent of puerperal septicæmia, made to the Paris Academy of Sciences, are of great interest. He cultivated the puerperal virus in broth made of lean beef, water and sea salt; in the open air, in oxygen with normal pressure, in carbonic acid, and in a vacuum. The longest series of cultures was made with a drop of the blood of a rabbit dead of puerperal peritonitis, and carried to twenty-six generations. The multiplication of microörganisms begins rapidly, but is not complete until the fourth or fifth day.

The microbes kill rabbits in from eighteen to thirty hours, and even in some instances guinea-pigs, animals that are not affected by inoculation of peritoneal pus. If the cultures are made in a vacuum or in an atmosphere of carbonic acid, the microbes are less numerous, but have greater activity.

Arloing attributes the failure of previous experiments to the culture-liquid used, for he has found that chicken-broth causes the activity of the microbes to cease after the first or second generation, but this activity was restored by next using beef-broth. When rabbits were inoculated with the virus which had been cultivated in a vacuum, they died with all the symptoms of septic poisoning without suppuration; if the virus cultivated in the air was used, the disease was slower, and the animals presented the lesions of fibrinous peritonitis; but if the virus had been weakened by cultivation in an unfavorable medium, the disease was still longer, and purulent inflammation affected the serous membranes.

It will be seen that these experiments, in great part, sustain the theory held by most clinical observers, viz., that puerperal septicæmia is essentially one, while multiform in its manifestations, and that its cause, while conveyed to the body by different media, is also single, in short, puerperal septicæmia is the result of a poison as specific in its action, as that of scarlatina. The puerperal condition creates the susceptibility to the poison, just as individuals at a particular time, by some unknown modification of the system, are susceptible to the scarlatinal poison, and take the disease, when they have escaped in a previous exposure. Further, as the scarlatinal poison varies in intensity at different times, so may the puerperal poison have like variations, and thus an explanation is given of one of the causes of the differences in the severity of the disease depending upon the latter poison.

Arloing, however, holds that if it is proved that the microbe of the puerperal virus is single, it is not proved that it may be peculiar to the disease, but only "that puerperality realizes the conditions favorable to its introduction, and to its evolution in the human organism."

SPLENECTOMY.

At the Thirteenth Congress of the German Surgical Association, von Hacker, of Vienna, exhibited a lymphoid sarcoma of the spleen, which had been successfully extirpated by Billroth on March 20th. Before removal, the oval tumor measured ten inches vertically and rather more than seven inches transversely. On median laparotomy, the convexity of the tumor was found to be free from attachments, but the omentum and a coil of the intestine were adherent to the hilus. The splenic artery and vein were divided between two ligatures, and rather more than an inch and a half of the adherent tail of the pancreas required removal with the thermocautery.

In the splenectomies hitherto recorded, the operation was done for wounds, hypertrophy, cysts, wandering spleen, or leukæmia, so that this is the first ever performed for sarcoma. In addition to this point, the case is, however, interesting from the fact that, three weeks later, there was a slight increase in the number of white blood-corpuscles, but there was no enlargement of the thyroid gland or the lymphatic glands, nor was there pain in the bones, or nervous disorders.

Credé, of Dresden, exhibited at the same Congress, a man, whose spleen he had removed two years and a half previously, on account of a cyst of the volume of a child's head. In this case, as in the preceding one, there had been no enlargement of the thyroid or lymphatic glands, and the man was apparently thoroughly well. In the discussion which followed, Czerny, of Heidelberg, stated that the woman from

whom he had removed a movable hypertrophied spleen five years previously, and who was still alive, exhibited no changes in the blood or in the organs referred to. Hence, we may infer that the spleen is not absolutely essential to life, and that its function, after extirpation, is assumed by the medulla of the bones and other lymphatic organs.

BLACKMAILING.

It is so rare that the confidential relations existing between a medical man and his female patients are taken advantage of to injure his reputation, or extort money from him, that he is in constant danger of forgetting the risks which are necessarily assumed in the practice of his profession, and that he may be entrapped when least suspecting it. Indeed, the very honesty of intention characteristic of the true physician may cause him to overlook those precautions which a bad man would naturally take.

A case which has recently been brought to the notice of the public in Philadelphia illustrates the dangers to which we are all subject. A physician, whose reputation has always been above reproach, was charged by a girl of bad character with having used instruments with the intent to produce abortion. She consulted him concerning a possible pregnancy, and he used a speculum, but no other instrument, to aid him in making a diagnosis. No sickness followed, and she never had any symptoms of miscarriage. Having previously treated her with success for an illness for which he received only thanks, he had the less reason to suppose that he was now being made the victim of a basely conceived blackmailing scheme, the character of which can be easily proven, but which, nevertheless, subjects him to great annoyance, anxiety, and expense.

The question naturally suggests itself, Cannot the physician protect himself against such unfortunate occurrences? To say that he should never examine a woman or treat her for a disease peculiar to her sex, without the presence of a third person, is to make a suggestion which it is clearly impossible to carry out in every instance. There are, however, certain precautions which should be generally observed. Under no circumstances should he consent to examine a young woman who seeks his advice for recent amenorrhœa except in the presence of a third party, or even prescribe for her an emmenagogue. The simple fact that a woman does not menstruate, in the absence of pregnancy, is nothing of itself. It is merely symptomatic. Under any circumstances, the patient is not likely to suffer harm by delay; and, as a rule, it is as well in obscure cases to give nature a chance to reassert herself. When examinations are made, extreme care should be observed in the use of the sound, as miscarriage has been induced more than once in manipulations when pregnancy was not even suspected.

In spite of the observance of these suggestions the practitioner will still run risks against which no set rules can guard him. But to be forewarned is to be forearmed, and the fact that a young woman seeks advice for amenorrhœa should cause him to be on his guard as to her motives until he has ascertained the true nature of her case and character.

CONSERVATISM AND RESECTION IN DISEASES OF THE JOINTS.

In an exhaustive paper contributed to the *Deutsche Zeitschrift für Chirurgie*, Bd. xx. Hefte 3 and 4, 1884, Caumont, of Münsterlingen, compares the relative advantages and disadvantages of conservative measures and resection in chronic inflammation of the articulations of the lower extremity, his statistics being based upon 281 cases treated in the clinic of Kappeler.

Of the entire number, the hip was affected in 129. Of these, 85 were managed conservatively, with 21 deaths, 22 recoveries with normal function, 38 recoveries with more or less loss of function, and 4 recoveries with the parts not healed. Of the 44 resections, 27 died, and 17 recovered. Hence the mortality was in favor of conservatism by 27.5 per cent.

The knee was the seat of disease in 130 cases, of which 95 were treated conservatively, and 35 by resection. Of the former, 27 died, 20 recovered with normal function, 46 recovered with more or less loss of function, and 2 remained unhealed. Of the resections, 14 died, and 21 recovered, the mortality being greater by 11.6 per cent. than that of the cases in which no operation was performed.

The ankle was affected in 22 examples. Of the 13 treated conservatively, 2 died, 6 recovered, 2 remained unhealed, 1 was still under treatment, and 2 recovered after amputation. Of the 9 resections, 3 perished, and 6 recovered with good use of the limb.

The lesson taught by this record is that, in inflammation of the hip-joint and knee-joint, expectancy is preferable to resection; and that resection secures a better result than attempts to save the joint in disease of the ankle, despite the fact that it yields a greater rate of mortality.

The intelligence of the death of Surgeon Joseph J. Woodward, U. S. A., which occurred near Philadelphia, on the 17th inst., will be received with sorrow by the profession which he so highly adorned. His valuable labors in connection with the Medical History of the War and the organization of the Army Medical Museum, together with his numerous contributions to our science and literature, have given him wide-spread reputation, and it is a cause for profound

regret that in the very prime of life his brilliant career should have been thus abruptly ended.

Next week we shall lay before our readers a sketch of his life and labors.

REVIEWS.

Sexual Neurasthenia (Nervous Exhaustion). Its Hygiene, Causes, and Treatment, with a Chapter on Diet for the Nervous. By George M. Beard, A.M., M.D., etc. (Posthumous Manuscript.) Edited by A. D. Rockwell, A.M., M.D., etc. 8vo. pp. xii., 270. New York: E. B. Treat, 1884.

Whatever may have been the faults of the author of this little book, published since his untimely death by his friend Dr. Rockwell, he had no lack of faith in the correctness of his own opinions. What he wrote about, he seemed to be sure about. This assurance of being right has some advantages and some disadvantages. In the case of Dr. Beard, it attached to him a certain number of followers; while, on the other hand, it detached from him many who, though admiring the daring of his imagination, could not fail to foresee that it promised as little permanent gain to him and to others as the wings on which Icarus once pleased himself with soaring above the solid earth. But while the general reputation of Dr. Beard was a precarious thing, carried up rather by flights of fancy than by solid reasoning, it cannot be denied that his zeal and ambition have contributed to the cause of science and humanity, by attracting the attention of the thoughtful to a more careful study of the phenomena for which he popularized the name "neurasthenia." And though his own notions in regard to them may have been exaggerated, yet they had a basis of truth which entitles them to serious consideration, and it is not proper to sneer at the share he had in securing for them the attention they deserve. The book before us is a part of Dr. Beard's work in this direction. It relates to an integral part of neurasthenia, and one which often sorely tries the information and skill of the practitioner. It is somewhat unfortunate that it comes at a time when several other books, of seemingly similar purpose, have appeared, overweighted with unclean details, and with the effect of prejudicing the reader against everything which belongs to the same class. But this book is not unclean. Though rambling and inaccurate, it is a readable contribution to the literature of sexual disorders, and is not open to any moral objections. As to its scientific value, truth and charity forbid us to say much. It is no better than the average of the author's work, and, we think, no worse. The concluding chapter, "On Diet for the Nervous," is, in our opinion, equally characteristic and erroneous, exhibiting nothing so much as the author's ingenuity in seeming to establish a point by citing facts which militate against it.

In saying this we are not oblivious of the time-honored maxim, "*Nil nisi bonum de mortuis*;" but hold it to be always subservient to a less sentimental but more needed motto, "*Nil nisi verum perpetuo*."

SOCIETY PROCEEDINGS.

INTERNATIONAL MEDICAL CONGRESS.

Eighth Session.

Held at Copenhagen, August 10th–16th, 1884.

Special Cable Dispatch from Our Own Correspondent.

Copenhagen, August 16th. The Eighth Session of the International Medical Congress has just adjourned, and the Organizing Committee, of which Prof. P. L. Panum is President, are the recipients of general congratulation on the very successful culmination of their efforts. On all sides the meeting is pronounced

A GREAT SUCCESS.

On Wednesday, the excursion to Elsinore occupied the entire day

A SPLENDID LUNCH

was served in the magnificent and venerable Castle of Kronborg, which was built towards the end of the sixteenth century, and from whose turrets were obtained superb views of the straits and of the neighboring countries.

On Thursday, the Sections met in the morning as usual, and in the afternoon, Sir William Gull, of London, on behalf of the Collective Investigation Committee of the British Medical Association, delivered, before the Congress in general meeting, an admirable

ADDRESS ON THE INTERNATIONAL COLLECTIVE INVESTIGATION OF DISEASE.

In conclusion, he presented a resolution providing for the appointment of an International Committee to undertake collectively the prosecution of pathological research. It was adopted, and the President appointed as the

AMERICAN REPRESENTATIVES ON THE COMMITTEE,

Dr. Abraham Jacobi, of New York, and Dr. Nathan S. Davis, of Chicago.

In the evening the Corporation of Copenhagen gave

A GRAND BANQUET

to twelve hundred members of the Congress. Upon its conclusion, the guests were conveyed in boats to Tivoli to view the illumination and fireworks, which was a superb sight, and fully thirty thousand persons were gathered to witness it.

On Friday the General Committee discussed the place of next meeting, and after carefully considering the various suggestions which had been offered, determined to recommend to the Congress to accept the invitation,

presented on behalf of the American Medical Association, to meet in Washington in 1887.

PROFESSOR TOMMASI-CRUDELI, of Rome, gave a

DEMONSTRATION OF MALARIAL GERMS,

and exhibited under the microscope a number of very good specimens.

PROF. RUDOLF VIRCHOW, of Berlin, then gave an

ADDRESS ON METAPLASIA,

which was in every respect worthy of its distinguished author, and was received with great applause.

THE KING OF DENMARK ENTERTAINED THE MEMBERS OF THE CONGRESS

in the evening, at a reception held in the Palace, and the occasion was graced by the presence of the members of the Royal Family. After a handsome collation had been served,

THE KING OFFERED A TOAST

to the health of the foreign members of the Congress, to which Sir William Gull, on their behalf, eloquently responded.

On Saturday morning, the work of the Sections, as laid down in the programme, was completed, and in the afternoon, in general meeting, PROF. P. L. PANUM, of Copenhagen, delivered an address

ON INVESTIGATIONS OF FOOD-RATIONS FOR MEN IN A STATE OF HEALTH AND OF DISEASE, ESPECIALLY IN HOSPITALS, INFIRMARIES, AND PRISONS OF DIFFERENT COUNTRIES.

Upon its conclusion, upon the recommendation of the General Committee, the Congress adopted, by an overwhelming vote and amid much applause, the invitation to hold its

NEXT MEETING IN WASHINGTON IN 1887.

The formal programme of the Congress having now been completed, Dr. John S. Billings, of the United States Army, Prof. Carl J. Rossander, of Stockholm, Sir Risdon Bennett, of London, and Prof. Virchow, of Berlin, in brief speeches, presented, on behalf of the foreign members, their best

THANKS FOR THE CORDIAL HOSPITALITY

with which they had been received, and congratulations on the very successful termination of the session.

PROF. PANUM, in a short address, thanked the members for their attendance at the Congress, and wished them a pleasant journey homeward, and long life and happiness. He then declared the session adjourned *sine die*.

A FAREWELL FESTIVAL

was given in the evening to the members of the Congress and their ladies, at which there was dancing and a handsome collation.

The universal expression of opinion is that the scientific aspect of the Congress has been good. The programme of work done in the Sections was full and included the presentation of a large number of valuable papers, and the demonstration of numerous interesting pathological specimens. The Section meetings were well attended and the discussions were actively participated in.

In dispersing to their homes the members will carry with them most pleasant recollections of Danish hospitality and of the Copenhagen Meeting of the International Medical Congress.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, June 2, 1884.

THE VICE-PRESIDENT, D. HAYES AGNEW, M.D., IN THE CHAIR.

DR. W. W. KEEN read a paper on

SO-CALLED ABSCESSES OF THE FRONTAL AND MAXILLARY SINUSES, AND ESPECIALLY ON THE VALUE OF PERCUSSION AS A MEANS OF DIAGNOSIS, AND THE PROPER OPERATIVE MEASURES FOR THEIR RELIEF.

(See THE MEDICAL NEWS, August 16, 1884, page 172.)

DR. GARRETSON, who was present by invitation, said that this paper covers the ground so completely that there is little to be added. He would remark, however, that very frequently one can get through the back part of the canine fossa. The best place to make the opening is where the roots of the molar teeth come in contact with the floor of the antrum. In partially dentulous arches, that is, where the teeth have been lost, and there is disease of the antrum, this may not show itself externally, but on running the finger along the part, the bone will be found so thin that it will bend. In one case in which there was no external evidence, he made a cut preparatory to opening the antrum, and at once the knife went into that cavity, the bone being absent.

There is another point regarding alveolar-dental abscesses. They occur at the roots of the teeth, and are in relation with the mucous membrane of the antrum, and may discharge into that cavity. There we have a partial abscess of the antrum, and the bone is denuded of its mucous membrane and imperfectly developed periosteum.

He had been struck with the fact that many cases treated as nasal catarrh are quickly remedied by perforation of the antrum and application of remedies to the antrum. *Vice versâ*, there may be nasal trouble which shows itself as antral disease, where, although the antrum is perforated and remedies are applied to its surface, but little benefit may be afforded. There is a very intimate surgical relation between the two parts. It has been his experience that disease of the antrum is quite rare.

DR. R. J. LEVIS said that he had once performed the operation of bringing a thick cord down through the nares and another cord through an incision made above, tying the two together and allowing the patient to wear it for a considerable length of time. The principle is to establish thorough drainage through the normal tract.

In regard to abscess of the antrum, he has made the opening through the maxillary bone above the alveolus. He thought that surgeons have had difficulty in keeping these wounds open so as to keep up thorough drainage. He has been in the habit of keeping them patulous by the use of thick leaden wire. He uses a loop of leaden wire, pressing the loop in as strongly as possible, and allowing the ends to project underneath the cheek, so as to give no inconvenience. He has under treatment two patients, one of whom has been wearing this leaden wire for a number of years, and says that he cannot get along without it.

Dr. Brinton said that as regards the influence of injuries to the infraorbital canal in producing abscess of the antrum, the worst case of antral abscess which he ever saw followed an excision of the infraorbital nerve which he performed some years ago. The abscess followed the operation in a short time, and lasted for a long time.

Dr. Keen, in closing the discussion, remarked that these two cases are the only ones which he had seen, and that the disease is rather rare. He had not the slightest difficulty in keeping the wound open sufficiently to wash the cavity out by passing a small Nélaton catheter. He kept it open until the discharge entirely disappeared, which was in six or seven days.

NECROSIS OF HUMERUS: AMPUTATION AT SHOULDER.

Dr. Willard presented the specimens; the first being a *humerus* injured by a Minie-ball in 1863, resulting in a slow osteomyelitis, which extended over twenty-one years, and terminated in the invasion of the entire bone, save the articulating surface at the elbow. During this long space of time, there had been alternating periods of discharge, and of closures of sinuses, but fragments of bone had never been seen since the first year after the accident.

When admitted to the wards of the Presbyterian Hospital the man was exceedingly anæmic and broken down, the discharge of pus averaging several ounces daily, and there was dulness on the left apex with slight cough. Soon afterwards he had a severe attack of erysipelas which invaded the whole arm, and still further reduced his strength, the temperature rising to 104.5°. The bone, felt through the various sinuses was denuded and roughened. After full recovery and a thorough tonic course of treatment, an exploratory incision revealed a total necrosis without involucrum, the dead fragments being movable upon each other and threatening complete fracture.

Three weeks later, after putting the patient in the best possible condition, amputation of the shoulder was performed. From the moment of the division of the muscles the shock was most profound, and, rallying powers being wanting, he sank in six hours.

At the operation the glenoid cavity was found diseased, but, owing to the patient's condition, the head of the scapula was not removed. The head of the humerus was entirely denuded of cartilage, a large pus-cavity occupied its interior, and it was only united to the shaft by fibrous bands of inflammatory tissue. The entire upper third of the bone had become divided into several sequestra, but there was no attempt at the formation of new bone. From the upper third to the condyles the surface was partially denuded, and was generally roughened and thickened, showing that no resection save of the complete bone, together with the head of the scapula, would have been of any service.

Dr. Willard then exhibited the specimens from a case of

LARGE IRREDUCIBLE UMBILICAL HERNIA, WITH STRANGULATION OF A FRESHLY ENTERING LOOP OF INTESTINE,

which particularly illustrated the ease with which a serious trouble may be overlooked.

The patient was a very fat woman, aged seventy-six, who had been in the hospital for months with leg ulcers, accompanying extensive valvular disease. One morning she was noticed to be vomiting as the surgeon passed through the ward, but she complained of no pain and had had a passage from the bowels upon the previous day. An examination of the ulcers showed them to be in a sloughing condition, the granulations being almost gangrenous. The ejected matters were only bilious, and one dose of a quarter grain of morphia and the same of calomel checked even nausea. There was slight fever, but no pain. At the evening visit the resident physician found her quite comfortable, but eliciting the fact of an old umbilical hernia which she had previously concealed from him and all others, he examined it thoroughly but could discover no symptoms of tenderness or pain. During the night without complaint of pain, and without further vomiting, she died.

The hernial tumor was of the size of a large fœtal head. The peritoneum was adherent, opaque within the tumor and around the margin of the neck, and the cavity contained a sero-sanguinolent fluid. The contents of the sac, which were irreducible, were mesentery, several feet of small intestines, and a portion of the transverse colon, thoroughly agglutinated and adherent to the walls. In addition to the old contents, a long loop of small intestine had recently entered through the opening, which was about three inches in diameter, and had been so constricted that peritonitis had supervened, as was shown by congestion of the entire tract. At the point of greatest strangulation this redness was intensified almost to blackness, and gangrene would speedily have followed. After death, this loop was reduced with ease, and the constriction could be scarcely discovered.

The left ventricle of the heart was thickened. At the root of the mitral valve was a calcareous ring, almost bony in consistence, surrounding three-fourths of the circumference. The aorta was dilated to twice the normal size.

Lungs healthy; liver enlarged, with some opacity of the capsule of Glisson.

Acini distinct; gall-bladder small; walls thickened, and mucous lining almost destroyed; gall-stones numerous; left kidney enlarged, mottled, and grayish; right, fatty and congested.

The case was of interest, as it showed a strangulation with absence of all of the ordinary symptoms, yet the patient died from the incipient shock of developing peritonitis.

LYMPHOMATA OF THE AXILLA.

Dr. Ferdinand H. Gross exhibited thirteen lymphoid tumors, of various sizes, which he had removed from the left axilla of a female patient, at the German Hospital. The patient was twenty-one years of age.

Her family history furnished no cause for believing that the disease had been inherited; her grandparents had lived to be quite old, and her parents were still living and in good health, as were also her brothers and sisters. She had never been sick until after her arrival in this country, where she has lived about a year, following the occupation of a servant-girl. During the last six months she had been troubled with indigestion and constipation, and when admitted to the hospital was affected with erythema of the left leg. Her temperature was slightly elevated, and the pulse was rapid and weak. The bowels were constipated, and there was loss of appetite. The erythema was of a mild character, and yielded promptly to the use of laxatives and astringent local applications. About five months previously she had had a similar affection of the other leg. In the left axilla there existed a growth, or growths, forming a mass of considerable size. Of this, however, the patient made very little complaint, saying that it did not now cause her any inconvenience, except when she used her arm a good deal—though it had at one time given her some pain. She noticed this enlargement for the first time ten or twelve weeks ago. But, of course, its origin dates farther back, as it had when discovered already attained nearly the size of a hen's egg. The conglomerate mass was now firmly bound down against the thoracic side of the axilla, but in the apex of that space, near the large bloodvessels and nerves, the attachments were less rigid. The tumor, as a whole, imparted a hard, elastic feeling on being manipulated, and was lobulated, but not painful. The mamma was not involved in the disease, and no other glandular enlargements were anywhere discovered.

The patient promptly consented to submit to an operation, and on the twenty-seventh of May, five days ago, she was etherized, and the thirteen tumors here presented were removed. A vertical incision, about four and a half inches in length, was made through the integument and fascia covering the mass, and the dissection continued in this line until the capsule of the first and largest of the growths was reached. After this, there was little use made of the knife, except here and there to open a capsule, or to divide some restricting bands. This done, the enucleation of all the tumors was readily completed with the fingers. The largest in the collection was about the size of a goose's egg, while there are several not larger than hen's eggs, and still others as small as filberts. They had not been fused into one mass by any inflammatory process, and were enucleated one after another. The second one in size was tightly bound under the great pectoral muscle, and extended to the under surface of the collar-bone. The hemorrhage was inconsiderable, and only one small vessel required a ligature. The cavity was thoroughly washed out with a solution of bichloride of mercury, a drainage-tube inserted, and the edges of the wound brought together by sutures. The external dressing was saturated with the antiseptic solution mentioned, and was not disturbed for forty-eight hours. It is now the fifth day after the operation, and the patient is progressing favorably. The wound looks well, and is almost entirely healed. There has been no microscopic examination, but from the general appearances of the tumors, and from the cut surfaces, there is no doubt that they are of a lymphoid character. The larger ones can hardly be regarded as being simply hyperplastic, but rather neoplastic.

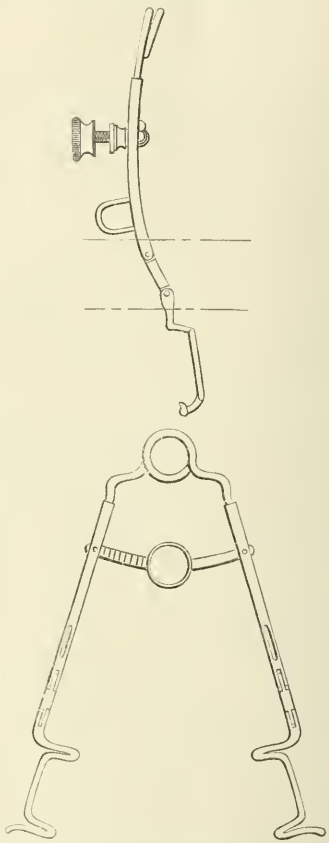
A committee was appointed to make a microscopic examination of the growths.

NEW INVENTIONS.

A MODIFICATION OF THE STOP-SPRING SPECULUM.

BY T. D. MYERS, M D.,
OF PHILADELPHIA

FINDING the end of the spring or stop-speculum greatly in the way in ophthalmic surgery, I sought to do away with the inconvenience of the instrument by having a double joint placed between the retractors and the spring. The cut shows the modification, which



enables the operator to depress the end of the speculum out of the way, or even to introduce it on the nasal side, where it will rest on the nose, leaving the temporal side of the eye entirely free to the operator. The instrument was made by Kolbe, of Arch Street.

NEWS ITEMS.

Dr. Koch on the Cholera and the Comma Bacillus.—An important conference upon cholera was held in Berlin, at the office of the Imperial Board of Health, on July 26, the proceedings of which appear in full in the *Berliner klinische Wochenschrift*, of August 4, and have been translated in *The Lancet* of August 9. There were present, Drs. v. Bergmann, Coler, Eulenberg, B. Fränkel, Gaffky, Hirsch, Koch, Leyden, S. Neumann, Pistor, Schubert, Skreczka, Struck, Virchow, and Wolffhügel.

The conference had been called at the instance of the Berlin Medical Society, whose President, Prof. Virchow, explained that it was thought advisable Dr. Koch should, in the first instance, give a demonstration of his work before a smaller body than the whole Society, so that the proceedings might be fully reported in the medical press. Before the meeting, Dr. Koch exhibited microscopical specimens and drawings of the cholera bacillus, and demonstrated the method of its preparation and cultivation. The preparations included specimens of choleraic dejections dried on covering-glasses, stained with fuchsin or methyl-blue, and examined with oil immersion, one-twelfth, and Abbe's condenser; also sections of intestine preserved in absolute alcohol, and stained with methyl-blue. There were also cultures in gelatine, etc.

Dr. Koch commenced by remarking that what was required for the prevention of cholera was a scientific basis. Many and diverse views as to its mode of diffusion and infection prevailed, but they furnished no safe ground for prophylaxis. On the one hand, it was held that cholera is a specific disease originating in India; on the other, that it may arise spontaneously in any country, and own no specific cause. One view regards the infection as conveyed only by the patient and his surroundings; the other, that it is spread by merchandise, by healthy individuals, and by atmospheric currents. There is a like discrepancy in the views on the possibility of its diffusion by drinking-water, on the influence of conditions of soil, on the question whether the dejecta contain the poison or not, and on the duration of the incubation period. No progress was possible in combating the disease until these moot-questions of the etiology of cholera are decided. Hitherto, the advances in knowledge upon the etiology of other infective diseases have done little toward the etiology of cholera. These advances have been made within the last ten years, during which time no opportunity—at least not in Europe—has occurred to pursue researches; and in India, where there is abundant material for such research, no one has undertaken the task. The opportunity given by the outbreak of cholera in Egypt, last year, to study the disease before it reached European soil was taken advantage of by various governments, who sent expeditions for the purpose. He had the honor to take part in one of these, and, in accepting it, he well knew the difficulties of the task before him, for hardly anything was known about the cholera poison, or where it should be sought; whether it was to be found only in the intestinal canal, or in the blood, or elsewhere. Nor was it known whether it was of bacterial nature, or fungoid, or an animal parasite—*e. g.*, an amœba. But other difficulties appeared in an unexpected direction. From the accounts given in text-books, he had imagined that the cholera intestine would show very slight changes, and would be filled with a clear, "rice-water" fluid. He had not fully recollected the conditions met with in post-mortem examinations he had formerly made, and was, therefore, at first surprised to meet with quite a different state of things. For he soon found that, in a large majority of cases, remarkably severe lesions were present in the intestines. In other cases, the changes were slighter, and eventually he met with some which to a certain extent corresponded with the type described in text-books. But it was some time, and after many inspections, before he was enabled to interpret correctly the varied changes met with.

In spite of a most careful examination of all other organs and of the blood, nothing was found to establish the presence of an infective material, and attention was finally concentrated on the intestinal conditions. There were cases in which the lower segment of the small intestine, most marked immediately above the ileo-cæcal valve, extending thence upwards, was of a dark, reddish-brown color, the mucous membrane being covered with superficial hemorrhages. In many cases, the mucous membrane appeared to be superficially necrosed, and covered with diphtheritic patches. The intestinal contents in such cases were not colorless, but consisted of a sanguinolent, ichorous, putrid fluid. Other cases showed a gradual transition to a less marked change. The redness was less intense, and was in patches, whilst in others the injection was limited to the margins of the follicular and Peyerian glands, giving an appearance which is quite peculiar to cholera. In comparatively few cases were the changes so slight as to consist in a somewhat swollen and opaque condition of the superficial layers of the mucous membrane, with delicate rosy-red injection, and some prominence of the solitary follicles and Peyer's patches. In such cases, the intestinal contents were colorless, but resembling meal-soup rather than rice-water. In only a solitary instance were the contents watery and mucoid.

Microscopical examination of the intestine and its contents revealed, especially in the cases where the margins of Peyer's patches were reddened, a considerable invasion of bacteria, occurring partly within the tubular glands, partly between the epithelium and basement membrane, and in some parts deeper still. Then he found cases in which, besides bacteria of one definite and constant form, there were others also accumulated within and around the tubular glands, of various size, some short and thick, others very fine; and he soon concluded that he had to do here with a primary invasion of pathogenic bacilli, which, as it were, prepared the tissues for the entrance of the non-pathogenic forms, just as he had observed in the necrotic, diphtheritic changes in the intestinal mucosa and in typhoid ulcers. Passing to speak of the microscopical characters of the contents of the bowel, Dr. Koch said that, owing to the sanguinolent and putrescent character of these in the cases first examined, no conclusion was arrived at for some time. Thus, he found multitudes of bacteria of various kinds, rendering it impossible to distinguish any special forms; and it was not until he had examined two acute and uncomplicated cases, before hemorrhage had occurred, and where the evacuation had not de-

composed, that he found more abundantly the kind of organism which had been seen so richly in the intestinal mucosa.

He then proceeded to describe the characters of this bacterium. It is smaller than the tubercle bacillus, being only about half or, at most, two-thirds the size of the latter, but much more plump, thicker, and slightly curved. As a rule, the curve is no more than that of a comma (,), but sometimes it assumes a semicircular shape, and he has seen it forming a double curve like an S; these two variations from the normal being suggestive of the junction of two individual bacilli. In cultures, there always appears a remarkably free development of comma-shaped bacilli. These bacilli often grow out to form long threads, not in the manner of anthrax bacilli, nor with a simple undulating form, but assuming the shape of delicate long spirals, a corkscrew shape, reminding one very forcibly of the spirochæte of relapsing fever. Indeed, it would be difficult to distinguish the two if placed side by side. On account of this developmental change, he doubted if the cholera organism should be ranked with bacilli; it is rather a transitional form between the bacillus and the spirillum. Possibly it is a true spirillum, portions of which appear in the comma shape, much as in other spirilla—*e.g.*, spirilla undula, which do not always form complete spirals, but consist only of more or less curved rods. The comma-bacilli thrive well in meat infusion, growing in it with great rapidity. By examining microscopically a drop of this broth-culture, the bacilli are seen in active movement, swarming at the margins of the drop, interspersed with the spiral threads, which are also apparently mobile. They grow also in other fluids—*e.g.*, very abundantly in milk, without coagulating it or changing its appearance. Also in blood-serum they grow very richly. Another good nutrient medium is gelatine, wherein the comma-bacilli form colonies of a perfectly characteristic kind, different from those of any other form of bacteria.

The colony when very young appears as a pale and small spot, not completely spherical, as other bacterial colonies in gelatine are wont to be, but with a more or less irregular protruding or jagged contour. It also very soon takes on a somewhat granular appearance. As the colony increases, the granular character becomes more marked, until it seems to be made up of highly refractile granules, like a mass of particles of glass. In its further growth, the gelatine is liquefied in the vicinity of the colony, which at the same time sinks down deeper into the gelatine mass, and makes a small thread-like excavation in the gelatine, in the centre of which the colony appears as a small white point. This, again, is peculiar; it is never seen, at least so marked, with any other bacterium. And a similar appearance is produced when gelatine is inoculated with a pure culture of this bacillus, the gelatine liquefying at the seat of inoculation, and the small colony continually enlarging; but above it there occurs the excavated spot, like a bubble of air floating over the bacillary colony. It gives the impression that the bacillus growth not only liquefies the gelatine, but causes a rapid evaporation of the fluid so formed. Many bacteria also have the power of so liquefying gelatine with which they are inoculated, but they never produce such an excavation with the bladder-like cavity on the surface.

Another peculiarity was the slowness with which the gelatine liquefied, and the narrow limits of this liquefaction in the case of a gelatine disk. Cultures of the comma-bacillus were also made in Agar-Agar jelly, which is not liquefied by them. On potato, these bacilli grow like those of glanders, forming a grayish-brown layer on the surface.

The comma-bacilli thrive best at temperatures between 30° and 40° C., but they are not very sensitive to low temperatures, their growth not being prevented until 17° or 16° C. is reached. In this respect, they agree with anthrax bacilli. Koch made an experiment to ascertain whether a very low temperature not merely checked their development, but killed them, and subjected the comma-bacilli to a temperature of —10° C. They were then completely frozen, but yet retained vitality, growing in gelatine afterwards.

Other experiments, by excluding air from the gelatine cultures, or placing them under an exhausted bell-jar or in an atmosphere of carbonic acid, went to prove that they required air and oxygen for their growth; but the deprivation did not kill them, since, on removing them from these conditions, they again began to grow. The growth of these bacilli is exceptionally rapid, quickly attaining its height, and, after a brief stationary period, as quickly terminating. The dying bacilli lose their shape, sometimes appearing shrivelled, sometimes swollen, and then staining very slightly, or not at all. The special features of their vegetation are best seen when substances which also contain other forms of bacteria are taken—*e.g.*, the intestinal contents of choleraic evacuations mixed with moistened earth, or linen, and kept damp. The comma-bacilli in these conditions multiply with great rapidity, so as far to outnumber the other forms of bacteria, which at first might have been in far greater abundance. This state of affairs does not last long; in two or three days, the comma-bacilli begin to die off, and the other bacteria to multiply. Precisely the same thing takes place in the intestine, where, after the rapid initial vegetation is over, and when exudation of blood occurs into the bowel, the comma-bacilli disappear, and putrefactive bacteria predominate. Whether the occurrence of putrefaction is inimical to the comma-bacilli has not been proved, but, from analogy, it is very probable. At any rate, it is important to know this for certain, for, if it be so, then the comma-bacilli will not thrive in a cesspit, and then further disinfection would be unnecessary. These bacilli thrive best in fluids containing a certain amount of nutriment. Experiments have not yet shown the limits in this respect, but Koch has found them capable of growing in meat-broth diluted ten times.

Again, if the nutrient medium become acid in reaction, their growth is checked, at least, in gelatine and meat infusion; but, singularly enough, they continue to grow on the surface of boiled potato which has become acid, showing that all acids are not equally obnoxious to them. But here, as with other substances which hinder their growth, they do not kill the bacilli. Davaine has shown that iodine is a strong bactericide. He experimented with anthrax bacilli in water to which iodine was added, and the bacilli were destroyed. But practically the organisms have to be dealt with in the alkaline contents of the bowel, or in the blood or fluids of the tissues, where iodine cannot remain in the free

state. Koch found that the addition of an aqueous solution of iodine (1 in 4000) to meat infusion, in the proportion of 1 in 10, did not in the least interfere with the growth of the bacilli in that medium. He did not pursue this line of inquiry, seeing that in practice larger quantities of iodine than that could not be given. Alcohol first checks the development of the comma-bacilli when it is mixed with the nutrient fluid in the proportion of 1 in 10, a degree of concentration which renders it impracticable for treatment. Common salt was added to the extent of 2 per cent., without influencing the growth of the bacilli. Sulphate of iron, in the proportion of 2 per cent., checks this growth, probably by precipitating albuminates from the fluids, and possibly also by its acid reaction; certainly it does not seem to have any specific disinfecting action—*i. e.*, in destroying the bacilli. Indeed, Koch thinks that the admixture of sulphate of iron with fecal matter may arrest putrefaction and really remove what may be the most destructive process to the comma-bacilli. Hence, he would distinguish between substances which merely arrest putrefaction and those which are bactericidal: for the former may simply serve the purpose of preserving the infective virus. Among other substances which prevent the growth of the comma-bacilli may be mentioned: alum, in solutions of the strength 1 in 100; camphor, 1 in 300; carbolic acid, 1 in 400; oil of peppermint, 1 in 2000; sulphate of copper, 1 in 2500 (a remedy much employed, but how much would really be needed merely to hinder the growth of the bacilli in the intestine!); quinine, 1 in 5000; and sublimate, 1 in 100,000.

In contrast with the foregoing measures for preventing the growth of these bacilli is the striking fact that they are readily killed by drying. This fact is proved by merely drying a small drop of material containing the bacilli on a cover-glass, and then placing this over some of the fluid on a glass slide. With anthrax bacilli vitality is retained for nearly a week; whereas, the comma-bacillus appears to be killed in a very short time. Thus it was found that, although vitality was retained — depending largely upon the number of bacilli—for a short time, yet withdrawal of the nutrient fluid for an hour or even less often sufficed; and it never happened that the bacilli retained vitality after a deprivation lasting twenty-four hours.

These results would seem to point to the fact that the comma-bacillus does not, like the organisms of anthrax and vaccinia, pass into the resting state (Dauer zustand) by drying; and, if so, it is one of the most important facts in the etiology of cholera. Much, however, remains to be done, especially with regard to the soiled linen of cholera patients being kept in a damp state. He found that in soiled articles, when dried for a time, varying from twenty-four hours and upwards, the comma-bacilli were quite destroyed. Nor was the destruction delayed by placing choleraic excreta in or upon earth, dry or moist, or mixed with stagnant water. In gelatine cultures, the comma-bacilli can be cultivated for six weeks, and also in blood-serum, milk, and potato, where anthrax bacilli rapidly form spores. But a resting state of the comma-bacilli has never been met with—a very exceptional thing in the case of bacilli; and another reason why the organism must be regarded rather as a spirillum than a bacillus. For the spirilla require only a fluid medium, and do not, like the anthrax bacilli, thrive in the dry state. It is quite unlikely that a resting state of the comma-bacilli will ever be discovered, and, moreover, its absence harmonizes with our knowldege of cholera etiology.

(To be concluded.)

Cholera.—The British steamship "Bracadaile," from Calcutta, June 4, and St. Lucia (West Indies), August 16, is en route to New York with reported cholera on board. She lost eighteen out of twenty-eight cases before reaching St. Lucia, and had 651 coolies on board. No apprehension is felt regarding this vessel, as the health officer at New York is on the lookout for her.

Resection of the Pancreas and Pylorus.— At the meeting of the Gesellschaft der Aerzte, of Vienna, on March 28, Dr. von Hacker presented a woman who had been operated on by Prof. Billroth, one month previously, for carcinomatous disease of the pylorus, involving the mesentery, intestine, and pancreas. The adhesions were torn or cut loose, and the affected portion of the pancreas was resected. The patient was quite well when exhibited.— *Wiener med. Wochenschrift*, April 5, 1884.

Gastrostomy.—The preliminary operation for gastrostomy was performed, on May 14, by Mr. Charles McNamara, on a woman, æt. 51 years, for obstruction of the œsophagus. The stomach was opened on the seventh day after the preliminary operation. The patient has thus far made a very good recovery, and can now swallow fluids.—*Lancet*, August 2, 1884.

Yellow Fever.—One case of yellow fever bas been reported by Passed Assistant Surgeon Guitéras, of the Marine-Hospital Service, taken from the U. S. steamer "Galena," at Key West. Dr. Guitéras reports it as a sporadic case, and no danger is anticipated of the disease gaining a foothold at that port.

The cases taken from the schooner "J. Taylor," at Cape Charles Quarantine Station, were decided by Passed Assistant Surgeon Irwin to be Chagres or Panama fever—the death by fever of one of the crew before reaching quarantine was regarded as suspicious.

What is Expected of the Washington International Congress.—Our sprightly London contemporary, *The Medical Times*, says: "It is not to be expected that the Congress at Copenhagen will be as big or as brilliant an affair as the London Congress. To match that, or to 'whip' it, we must wait another three years, until the United States are given an opportunity of showing what they can do at Washington."

Dr. Osler and the Chair of Clinical Medicine in the University of Pennsylvania.—Our excellent contemporary, *The Canada Medical and Surgical Journal* (Montreal), in referring to the probable appointment of Dr. Osler to the Chair of Clinical Medicine in the University of Pennsylvania, says: "If Dr. Osler should finally accept this appointment, whilst recognizing its appropriateness, we could not but feel that his removal involved a serious loss both to McGill University and to this city."

RESIGNED FROM THE MARINE-HOSPITAL SERVICE.—Passed Assistant Surgeon John C. Fisher, of the U. S. Marine-Hospital Service, has resigned, to take effect September 30. Dr. Fisher was on duty at the Surgeon-General's Office, Washington, for nearly four years, and the service loses a valuable and faithful officer by his resignation.

THE AMERICAN DERMATOLOGICAL ASSOCIATION.—The eighth annual meeting of this Association will be held at Cranston's, on the Hudson, near West Point, on the 27th, 28th, and 29th of the present month. It is expected that the following papers will be read at the meeting:

A Case of General Idiopathic Atrophy of the Skin; A Case of Xanthoma Multiplex; A Case of Sarcoma Cutis (with supplementary account of a case previously reported), by Dr. W. A. Hardaway, of St. Louis.

A Clinical Contribution to the Study of Lupus Erythematosus of the Hand, by Dr. J. Nevins Hyde, of Chicago.

Suggestions Respecting the Treatment of Acne and Acne Rosacea in the Male Subject, by Dr. S. Sherwell, of Brooklyn.

A Case of Unilateral Chromidrosis, Cases of Arsenical Dermatitis, by Dr. James C. White, of Boston.

Dermatitis Herpetiformis: its Relations to Impetigo Herpetiformis, by Dr. L. A. Duhring, of Philadelphia.

On a Peculiar Scaling Affection of the Glans and Prepuce, by Dr. R. W. Taylor, of New York.

On Miliaria and Sudamina, by Dr. A. R. Robinson, of New York.

The Neuropathic Theory of Herpes Zoster. Is it Sustained by Clinical Facts? by Dr. Geo. H. Rohé, of Baltimore.

A Case of Late Cutaneous Syphilis (Acneiform Syphiloderm of the Nose), illustrating the occasional necessity of large doses of potassium iodide. A Case of Vitiligo Involving the whole Surface, by Dr. H. W. Stelwagon, of Philadelphia.

THE CANADA MEDICAL ASSOCIATION will hold its annual meeting on Monday next at Montreal, and an unusually large number of attractive papers is announced.

THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE will meet in the same city on the following Wednesday, August 27.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE will meet in Philadelphia on September 4, and it is expected that upwards of four hundred of the prominent members of the British Association will be present, including Prof. Flower, of the Royal College of Surgeons, London; Mr. Alfred Godson, of Manchester; Mr. Alfred C. Haddon, Professor of Zoölogy in the Royal College of Science, Dublin; Dr. John McKendrick, Professor of Institutes of Medicine in the University of Glasgow; Mr. H. N. Moseley, Professor of Anatomy in the University of Oxford; and Mr. Lawson Tait, of Birmingham.

THE INTERNATIONAL CONGRESS OF HYGIENE assembled at the Hague on Thursday. Among those announced to deliver addresses were Dr. Pasteur, of Paris, and Dr. Stephen Smith, of New York.

THE BRITISH MEDICAL ASSOCIATION will hold its annual meeting in 1885 at Cardiff, and Dr. W. T. Edwards, of Cardiff, is the President-elect.

SIR PRESCOTT GARDINER HEWETT, Bart., F.R.S., has been appointed one of Her Majesty's Sergeant-Surgeons in Ordinary, in the place of the late Cæsar Hawkins.

SIR ERASMUS WILSON.—At the meeting of the Royal College of Surgeons, on August 5, the large honorary gold medal was awarded to Sir William James Erasmus Wilson, in recognition of his liberal contributions to the Museum, the Pathological Curatorship, and in the foundation of the professorship with which his name is associated.

NOTES AND QUERIES.

SCHOOL FOR CHILDREN OF DEFECTIVE INTELLECT.

To the Editor of THE MEDICAL NEWS.

SIR: The school for children of slowly developing intellect, alluded to in my letter to THE MEDICAL NEWS last fall, was started with two pupils. The results have been so encouraging in these two cases as to lead Miss Bancroft to reopen in the coming fall. She will receive then boarding as well as day pupils. The number of the former will be limited to ten. Her qualifications for such a task are so unusual that I can commend her most unreservedly to the confidence of any who may need such a school for their patients or others. Her address is—Miss Margaret Bancroft, Haddonfield, N. J. Yours truly,

W. W. KEEN, M.D.

PHILADELPHIA, 1729 CHESTNUT ST.,
August 15, 1884.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 12 TO AUGUST 18, 1884.

BARTHOLF, J. H., *Captain and Assistant Surgeon.*—Relieved from duty at Vancouver Barracks, Washington Territory, and ordered to take station at Portland, Oregon.—*Par. 1, S. O. 114, Headquarters Department of Colorado,* August 1, 1884.

HEIZMANN, C. L., *Captain and Assistant Surgeon.*—Ordered to proceed to Fort Ontario, N. Y., and report for duty.—*Par. 3, S. O. 163, Headquarters Department of the East,* August 13, 1884.

KANE, JOHN J., *Captain and Assistant Surgeon.*—Granted leave of absence for one month.—*Par. 1, S. O. 160, Headquarters Department of the East,* August 10, 1884.

BIRMINGHAM, H. P., *First Lieutenant and Assistant Surgeon.* Granted one month's leave of absence.—*S. O. 162, Headquarters Department of Missouri,* August 12, 1884.

WOODWARD, J. J., *Major and Surgeon.*—Died August 17, 1884.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLV. SATURDAY, AUGUST 30, 1884. NO. 9.

ORIGINAL LECTURES.

SOME POINTS IN THE DIAGNOSIS BETWEEN PSOAS ABSCESS, ANEURISM, HERNIA, AND MALIGNANT DISEASE.

A Clinical Lecture delivered at the Hospital of the University of Pennsylvania.

BY JOHN ASHHURST, JR., M.D.,

PROFESSOR OF CLINICAL SURGERY IN THE UNIVERSITY OF PENNSYLVANIA.

(Reported by William H. Morrison, M.D.)

GENTLEMEN: The first case which I bring before you to-day is of great interest in regard to the question of diagnosis. I cannot say that I am absolutely certain in my own mind as to the nature of the case, although, after a very careful examination, I have come to a conclusion different from that which I at first entertained. This patient presented himself at the hospital one week ago with a large tumor of the groin which you now see. I made a hasty examination just before the last lecture, and my impression was that it was a case of malignant disease, probably sarcoma, with cystic degeneration, involving some of the glands of this region. Had I brought the patient before you then, I should have said, from the hasty examination which I had made, that this was a case of malignant tumor. After the lecture I examined the patient more carefully, and then found reason to change my opinion. At the same time, I say that the case is an obscure one, and I am not absolutely positive as to my diagnosis, although I believe that I have determined the correct nature of the affection. This will, however, be shown by the exploration which I intend to make.

The various affections which might cause a tumor in this position are: 1. A solid tumor, malignant or otherwise; 2. Aneurism of the upper portion of the femoral artery; 3. Femoral hernia; 4. A cyst of some kind; 5. A psoas abscess, originating either in the sheath of the psoas muscle, or having made its way into the sheath of that muscle gradually passing downwards until it appears in this situation; and, 6. Varix of the saphena vein, for which, however, this tumor could hardly be mistaken. The points on which we rely in making the diagnosis are partly anatomical and partly dependent on the results of careful examination.

Let us first consider aneurism of the femoral artery. Although this is in the course of the artery, I do not think that it is an aneurism. There is no pulsation whatever, which could hardly be the case in an aneurism as soft as this tumor is. There is no bruit. On placing my ear over the tumor, no sound is heard. In some positions of the tumor, there is a slight transmission of sound from the artery, but there is no characteristic bruit. There is no swelling of the limb, nor change in the pulse below the tumor. Finally, the artery can be traced on to the tumor to a certain extent, and then it seems to disappear beneath it. If this were an aneurism, we should probably find that it was more or less continuous with the line of pulsation above, although, of course, a sacculated aneurism might overlap the artery to such an extent as to appear to be a separate tumor.

Next, in reference to the points in favor of malignant growth. In the first place, the history points somewhat in that direction. The patient can give no cause for this swelling. He is aware of no injury which might have caused it. The only history is that it began as a small lump above and grew downwards. It was also a soft tumor. This fact would tend to show that it was not a malignant growth. If this were a sarcoma with secondary cyst, it would at first have been a hard tumor and the softness associated with the cyst would have been a secondary development.

Then as to the question of hernia. This is not in the position of a femoral hernia. The hernia comes down on the inner side of the femoral vessels, and when it is strangulated the constriction is at the junction of Hey's and Gimbernat's ligament. Tracing this tumor upwards, I find that on the inner side of the femoral vessels, Poupart's ligament is perfectly distinct, but on the outer side of the vessels there is a marked extension of the swelling, which is very tense, elastic and fluctuating, and which has passed a little above Poupart's ligament. This of itself would negative the idea of femoral hernia. On the other hand, we know that psoas abscess comes down in the sheath of the muscle, often pressing the fibres of the muscle apart, and is almost always found on the outer side of the vessels. Here then is an anatomical point which would lead us to think that this was an abscess. There is another symptom present which is observed in both hernia and abscess, that is, a marked impulse is transmitted to this tumor when the patient coughs. This I cannot show to you now as the patient is under ether. This was the first point which diverted my mind from the theory of malignant growth. This is seen in hernia and in any large abscess originating in the abdominal cavity. A solid tumor situated below Poupart's ligament would not receive an impulse from coughing. This point leads us almost certainly to hernia or a collection of fluid, and the anatomical point in regard to the position of the tumor in reference to the femoral vessels would exclude hernia.

Our diagnosis is therefore narrowed down to either psoas abscess or a cyst of some kind originating within the abdomen. It might be a hydatid cyst, for these are found in all parts of the body. There are, however, some points which favor abscess rather than a cyst of this kind. One of these is the œdema over the prominent portions of the tumor. This is very significant of abscess. The tumor is then evidently pointing. In this the tumor has changed its appearance since last week; there are now several prominent nodules, like grapes, which were not present a week ago. They were rather more prominent two days ago than they are at present. By carefully feeling them, I can satisfy

myself that at these points the subcutaneous fascia has given way, allowing the fluid to come to the surface. There are three or four points at which the swelling is beginning to point, but these are becoming fused together. If the swelling were left alone, it is probable that in two days more there would be only one large nipple-like process.

The tumor extends downwards to a considerable distance and is elastic at all points; last week it was much more solid. It appears to be limited to the position of the adductor group of muscles. I believe that this is a collection of pus beneath the muscles pushing them forwards.

There is one other point to which I may call attention. In psoas abscess, we often have a large collection of pus above Poupart's ligament and a small one below. In the present instance, the collection below is larger, but at the same time there is a fluctuating tumor in the iliac fossa, above the ligament. When I press upon the upper one, I find that the tension of the lower swelling is increased.

As I have said, after a careful examination and a consideration of all these points, I have come to the conclusion that this is a psoas abscess. I, however, can find no cause for such a condition. There is no evidence of spinal disease, and the patient is able to walk very well. Abscesses sometimes originate in the sheath of the psoas muscle from some irritation or from external influences without any connection with bone disease. When the abscess results from disease of the spine, it is, as a rule, better to let it alone. If there is no disease of the bone, or if such disease has apparently been cured, for abscess may remain as a sequel of disease of the spine, you may open the abscess and adopt some means to prevent a continuance of the suppuration.

What I propose to do first, is to confirm or disprove the diagnosis by the use of the exploring-needle. I am not very enthusiastic in the use of this instrument, for I believe that the surgeon should be able, in most cases, to make the diagnosis without it. At the same time, when the diagnosis is sufficiently formed to enable the surgeon to determine upon a plan of treatment, the needle may be used. If I were in doubt as to whether this was an aneurism or an abscess, I should hesitate to use the exploring-needle, because, although it would clear up the diagnosis, it might injure the patient. In the same way with hernia. If I thought that this might be a malignant tumor, I should hesitate in the use of the exploring-needle, unless I was prepared to adopt some radical measures for its removal. In aneurism, the use of the needle weakens the wall of the sac and increases the danger of rupture. In malignant growth, the needle produces irritation and probably increases the rapidity of growth. I think that the surgeon should not introduce the needle, unless he is prepared to do something further, if not immediately, at least within a short time.

If a few drops of pus follow the introduction of the exploring-needle, I shall introduce the aspirator, and if the instrument will work satisfactorily, remove the fluid with it. If this does not succeed, I shall make a small opening and get rid of the pus in this way. Having removed the pus, I intend to inject the cavity with a solution of carbolic acid (one to thirty) to hyperdistention, as was recommended by the late Mr. Callender. The object of this is not to carrry out any antiseptic method, and the advocates of the so-called antiseptic mode of treatment would not accept it as an antiseptic measure. The late Mr. Callender recommended this plan of treatment for the purpose of producing a healthy stimulation of the walls of the abscess, to increase the likelihood of healing, and, perhaps, prevent the recollection of the pus. I have used this method on several occasions, and usually with satisfactory results. If there were active disease of the spine, however, such treatment would be of little use, because the abscess would soon refill.

If I find no pus, I shall proceed no further at present, and the question will then arise whether or not we shall attempt to remove the tumor. I do not think that such an attempt would be advisable, for the tumor evidently extends into the abdomen. I, however, have as firm a faith as it is possible to have without sight, that we shall find pus.

I now introduce the exploring-needle, and at once pus, of the character found in a cold abscess, escapes. I shall now introduce the canula of the aspirator, but, as you see, the tube soon becomes clogged with some shreds of broken-down tissue. I shall therefore be compelled to make an opening with a bistoury. The opening that I make is a very small one. A large quantity of pus is escaping.

This ought to be a very instructive case to you. As I have already said, if I had brought this patient before you last week, after the hasty examination which I had made, I should have said that it was a case of malignant tumor, simply because I had not made a thorough examination. A careful examination satisfied me that in all probability it was an abscess. The neglect of this thorough examination would have led to an error of diagnosis. The anecdote is told of the Russian surgeon, Pirogoff, that on returning from a long journey through the cold he found in his waiting-room a patient with a fluctuating tumor in the region of the axilla, and suffering intense pain. It was, apparently, a large abscess. Desirous of giving relief as soon as possible, he introduced a knife, and a free flow of arterial blood followed. He had opened an aneurism. Mistakes of this kind have been made by the most eminent surgeons. But I believe that Mr. Holmes is right in saying that the mistakes have been due to the omission of some point of a careful examination. I would not say that the surgeon should never make a mistake, but we can say, from a study of the cases in which a mistake of this kind has been made, that some point has been omitted in the investigation. It is not the fault of Nature, but the fault of the surgeon who misinterprets Nature, that these mistakes are made.

I am now getting to the end of this collection, for blood is beginning to appear. Sometimes, if you continue, you can in these cases get pure blood from the wall of the sac. In making pressure, it is better to use a sponge than the unprotected fingers.

I am now ready to wash this out. The injection is made with an ordinary gum bag, holding about six ounces. The first bagful of fluid will be pressed out, but in the remaining injections the fluid will be allowed to remain, and we shall distend the sac to a greater extent than it was distended before it was opened, so that

the liquid shall come in contact with every part of the interior of the cavity. The liquid will then be again carefully pressed out, and a simple dressing applied.

If, in spite of this treatment, the pus continues to collect, I shall probably make a counter-opening, and introduce a drainage-tube. We shall probably prevent the reformation of pus to a certain extent by the use of this injection.

Having removed the carbolic acid solution, the opening is dressed with a little oiled lint, covered with oiled silk; a compress of oakum is placed over it, and a spica bandage is applied in order to make slight pressure. The bandage is put on with the limb somewhat flexed, so that when it is straightened the pressure will be increased.

ORIGINAL ARTICLES.

ON TUBERCULOSIS OF BONES AND JOINTS, AND ITS TREATMENT BY IGNIPUNCTURE.

BY ROSWELL PARK, A.M., M.D.,

PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF BUFFALO.

I DESIRE to begin my paper with a few general propositions, to be elaborated in its course as far as time and space may allow.

1st. Many affections of bone essentially inflammatory in their nature are considered to be simply affections of the periosteum, or are ascribed to rheumatism, or are overlooked until irreparable damage has been done.

2d. Excluding rheumatism, syphilis, and malignant disease, the great majority of chronic bone affections either have tuberculosis as their immediate cause, or else during their course acquire a tuberculous character by appreciable pathological processes.

Indeed, one might almost paraphrase Niemeyer's dictum of a few years ago, and say—"The chief danger for anyone suffering from bone disease is that it may become tubercular,"—supposing, of course, that it was not originally so.

3d. Certain of the *acute* bone diseases have so much of the tubercular character that we cannot well separate the two—*e. g.*, acute osteomyelitis.

4th. Accepting phthisis pulmonum as the commonest type of tuberculous disease, we shall find remarkable resemblances between diseases of this type in bone and lung, just as there is remarkable resemblance of anatomical structure. Mr. Savory has shown[1] this to advantage. The cancellous structure much resembles the parenchyma of lung-tissue; both are eminently spongy. In both a vascular halo surrounds the mass of tubercle, and in each, by the breaking down of deposit, a cavity is formed. The pleura bears much the same anatomical resemblance and physiological relation to the lung that the synovialis does to the bone-end; just as pleuritis is set up in phthisis, so is synovitis in tuberculous ostitis; just as adhesions tend to form in the pleural cavity, so do they in the synovial also; just as obliteration of internal veins causes prominent subcutaneous veins about the chest, so are the superficial veins enlarged about a tumor albus; just as a tubercular pleuritis may lead to an empyæma with all its disastrous consequences, so may a tubercular synovitis lead to a pyarthrosis (empyæma of the joint) with fungous ulceration and the like. In almost every feature, then, are the variable progress and effect of tubercle in bone and lung alike. Furthermore, as in the larger number of cases the tubercular affection seems to locate by preference in the extremities of the lungs—*i. e.*, the apices, so do we find that in bones it is most common in the vicinity of joints.

Despite the teachings of many English and American writers, I think we are compelled to acknowledge that the majority of chronic joint affections take their origin from diseased bone in their neighborhood. Barwell and others would have us understand that in morbus coxæ, for instance, the primary trouble is usually a synovitis; but it seems to me that a careful study of early symptoms and anatomical appearances must lead us to accept the views and teachings of the German and French writers, who, like Volkmann, Koenig, Kocher, and Lannelongue hold in striking accord that most of these joint troubles begin, not as arthropathies, but as osteopathies, and are preceded by a well-defined ostitis or osteomyelitis.

Various forms of primary bone trouble may lead to fungous joint disease; most frequent is fungous ostitis, which spreads by continuity of structure along the periosteum and capsular insertion. If it be a suppurative ostitis (which is less often observed, and may be mistaken for a suppurative osteomyelitis or "ostitis profunda"), it will usually occur at an age when the epiphyses are still well marked, and will then lead to purulent infiltration of the same with only a collection of serum in the joint, though perforation *may* ensue. Chronic suppurative osteomyelitis gives rise to the same condition by spreading, from continuity of structure, along the periosteum, or else, more rarely, perforation into the joint occurs. So, too, may a suppurative periostitis give rise to a condition much resembling the above. In all forms the joint affection increases in severity *pari passu* with the primary bone disease. Finally, the joint may be involved purely through necrosis of a bone-end, usually central. The more chronic the bone disease, the more likely it is to be masked by the more conspicuous joint affection; whereas, the more acute the inflammation in the bone, the more likely is it to be recognized. Moreover the disturbance in the joint may take place very early, even almost before the periosteum has become involved.

In other words, the most common primary alteration in bone is that known to the Germans as "ostitis fungosa." The cancellous structure is softened, the number of bony trabeculæ notably reduced, and replaced by a soft, vascular, young connective tissue. The extension into the joint is made by perforation by a similar process.

How one may recognize primary, but chronic ostitis of joint-ends is an important question. It is known that there are certain points of tenderness most frequently met with about inflamed joints. Naturally, points of peculiar sensitiveness to pressure are also symptomatic of osteal trouble. So it is well to em-

[1] Lancet, November 4, 1882.

phasize that circumscribed ostitis commonly occurs at those points to which attention has been thus called; the internal condyle of the femur, the external condyle and greater tuberosity of the humerus, the internal malleolus, for example. Moreover, the nearer the local affection to the joint surface the greater will be the sympathetic disturbance. Sometimes incapacity or limitation of motion is the first sign which attracts attention. Sooner or later atrophy of muscles becomes a prominent and diagnostic feature. I think it is now universally accepted that no bone trouble can long persist (with certain rare exceptions) without atrophy of soft parts as an accompanying feature, though sufficient stress is not laid upon the fact in the common teaching of the subject. As a rule, too, a joint may be incapable of actively functionating, even to a diagnostic degree, and yet permit a wide range of passive motion.

5th. I would emphasize the diagnostic significance of "starting" (osteocopic) pains at night; these are too often confounded with those of syphilis, but are to be differentiated by the entire absence of the other signs or symptoms of specific disease.

As the primary ostitis progresses, the symptoms of ordinary synovitis are added to those already present. Such a synovitis is peculiarly stubborn, though, perhaps, intermittent. This is even true to such an extent that when an apparently chronic synovitis (hydrops articuli) becomes intermittent there is good reason to suspect a bone lesion behind it. To this fact Roser has called particular attention. In such a case, with each slight exacerbation there is an obstinacy to treatment that seems most surprising.

Inside of the joint suppuration or proliferation may take place, at times, with very little apparent disturbance. Fluctuation can be detected, but tension is not greatly altered, and pressure is not more painful than before, perhaps even less so. At times the capsule seems no thicker than before, but in certain cases a large amount of thickening can be made out.

According to the nature of the bone lesion is the swelling; usually a more or less hard local elevation caused by periosteal thickening is felt. But when the primary lesion is near the surface and has lead to a suppurative periostitis, we may have a fluctuating swelling marking well its position; a (cold) abscess thus resulting will most always be very tender to pressure.

Another occasional symptom of the disease under consideration is the repeated formation of abscesses, which sometimes break spontaneously and heal, sometimes leave fistulous openings. Surely the picture of a tumor albus with one or several fistulæ is a familiar one to all. No attempt is made here to deny that abscesses may and do result from well-defined synovial inflammation, but they are *very* rare.

Finally, I will only here mention those muscular contractions by which the joint-ends are not only firmly pressed together, but kept in position most favorable for anchylosis, and by which great deformity and subluxation are produced.

When we come to discuss the causes of osteal inflammation, so often tuberculous, we have, first of all, to note this fact, that probably nine out of ten of them occur in patients of a tubercular (scrofulous) diathesis.[1] Just as we would give a more guarded prognosis were a scrofulous individual to have a chronic cough, and would redouble our efforts to conduct, in his case, a pneumonia or a pleurisy to a successful resolution, just so should we feel doubly anxious in case of injury or inflammation to the bones of similar individuals.

Undoubtedly in the list of causes trauma plays the most important *rôle*, either as a direct injury or as a disturbance to the nutritive supply from the immediately enveloping soft parts. A sprain or a dislocation may in this way be ample cause. Any disturbance, too, of the insertion of the capsule is a frequent cause of trouble.

Next to trauma, perhaps, stands syphilis, of which we have in this place little to say. And as further causes, if we may so denote them, are pregnancy and the puerperal state, and the condition, often one of marasmus, following the continued fevers and exanthemata. For instance, I have seen acute, and almost fatal, osteomyelitis of several long bones follow exposure during the menstrual epoch; another almost as severe case was a sequel of typhoid fever; and I have had to resect a knee-joint for a typical tuberculous trouble the first symptoms of which were presented during the fifth month of a first pregnancy, which got worse in spite of all treatment, so that the propriety of inducing premature labor was even seriously discussed in consultation, which improved as soon as labor terminated, but relapsed as soon as the illegitimate child was permanently removed from the breast, the whole case being similar to those which Barwell has described. But in each of these cases there was a well-marked diathesis and a deplorable history of family phthisical taint.

It is very evident, of course, that I am basing my pathology of the complaints under consideration on the tubercular basis. It is amazing to me that when continental authorities generally accept this idea so firmly, and not only base upon it their theories but their successful therapeutics, it finds such tardy recognition in the standard English and American text-books. What American text-book speaks of it in any but the most non-committal way? Take, for example, Agnew's *Surgery*, the latest representative American work; the author devotes a section to "Strumous Inflammation of Articular Extremities of Long Bones," in which he describes the ordinary naked-eye appearances of a fungous joint, divides the symptoms into three stages, and after saying a few words about the prognosis goes on at once to the treatment. Never a word about tuberculosis of bone as such. Nor elsewhere in the work can I find any information on the subject calculated to satisfy a searcher after knowledge. What author of a work in our tongue has the frankness to state that most all of our cases of hip-joint disease, for example, are due to that which really causes them—*i. e.*, tuberculosis of bone.

The latest representative English work is, of course, Holmes's *System* (London, 1883). This is more satis-

[1] *Vide* paper by Gibney, N. Y. Med. Journ., July, 1877, p. 6.

factory, provided only that one finds the right places, the article by Shaw and Barker being most so. And yet in this same work we find the editor himself saying (vol. ii. p. 304, note) "my opinion is that many of the deposits which are usually regarded as tubercles are masses of inspissated pus mingled with other inflammatory products, and that, rare as tubercle in bone is generally said to be, it is in reality still rarer." He then quotes Macnamara as holding more to the views already expressed in this paper, and adds: "Some of the German pathologists appear to regard every inflammatory production in which 'giant cells' and a 'reticulum' can be found as tuberculous, and then go on to assume for this tubercular product an auto-infecting property. All this, however, appears to me to rest on the slenderest basis of fact."

For our own part, while we call in question the statements of such an authority as Mr. Holmes with extreme diffidence, it is yet impossible to disbelieve the evidences of one's senses, which teach that tuberculous products do possess the extremely auto-infectious properties recognized by the continental authorities. As far as the writer's opportunities for observation have extended, it has seemed that the so-called strumous lesions of bone as well as of other parts were both more common and more carefully studied on the Continent than in Great Britain. A review of the literature of the subject leads one, also, to the same conclusion.

If, moreover, the presence of the *bacilli tuberculosis* counts for anything, it is proper here to state that the writer, like numerous observers abroad, is usually able to find them in the *débris* or pus from various bone and psoas abscesses, fungous joints, fistules, sinuses, etc., which he has thus learned to regard, and always to speak of as "tuberculous." And if failure to find the bacilli results in a certain percentage of efforts, in such broken-down material, we must not forget that it *is* broken-down, and often quite old and changed before the surgeon liberates it; which being the case, failure must necessarily at times result.

And here, even at the risk of being tedious, I think it well worth while to speak of the manner in which the specific microörganisms of tuberculosis play the part now assigned them as specific irritants. And in so doing, rather than use words of my own, I prefer to draw from the article by Shaw, and revised by Barker, above alluded to.[1] If this explanation is true for caries of the spine, it holds equally good for the other bones or parts of the body. I quote:

"The exponents of this view regard scrofula as a definite septic disease, characterized by proneness to low inflammation of the growing tissues of the body, the result of irritants introduced from without, and circulating in the blood. . . . These organisms taken up by the lymph radicles in the first place, are for the most part strained off, as it were, in the nearest lymphatic glands. It is by their aggregation and multiplication here that those cheesy masses so often found in glands—*e. g.*, of the neck, are supposed to be formed (Billroth). These caseous masses then are no longer regarded by pathologists holding this view as products of inflammation with secondary fatty degeneration, as first described by Virchow, but simply as colonies of microbia. They may, and usually do, eventually produce an inflammatory condition around them, but the material of which they are composed differs chemically and microscopically from the products of inflammation. Many of the microbia, however, are supposed to escape the straining action of the glands and thus gain admission to the general circulation. Arriving thus with the blood in the capillaries of the growing tissues, they not only interfere by blockage with the vitality of the latter, but act as direct irritants, producing either chronic congestion or (if agglutinated in large numbers) actual so-called cheesy deposits. These may then induce inflammation around them and themselves soften. . . . This aggregation of micrococci is held to be favored in bone by the arrangement of its vessels in wide lacunæ; hence the frequency of strumous disease in bone. . . . Particles of the cheesy deposit may be thrown off into the circulation, and be carried into some of the capillaries at a distance. Here they give rise to irritation and exudation of white blood-corpuscles, which form around them soft miliary granulations to which the name '*tubercle*' is given."

This explanation is not quite so complete as it should be made, but I give it because it is so refreshing to find it incorporated into any *text-book* in our language.

To this I would add that Weigert, perhaps more than anyone else, has helped to give explicitness to this fact of capillary embolism of tuberculous material. More than this, it is the only rational explanation which can be given of many cases of idiopathic caries of bone.

But I have said enough to outline and emphasize the more recent and soundest views concerning tuberculosis of bone and its frequency, and to serve as a basis upon which to construct, if possible, a rational therapeusis.[1] And first I must insist that tuberculosis when still a local disease is amenable to treatment, and can be—nay, frequently *is*—cured. We even know a pseudo-recovery from phthisis pulmonum. It is so difficult to cure partly because of the dissemination of the specific irritant, partly because of its frequent inaccessibility. But we know that superficial tubercular lesions accessible to the knife or the sharp spoon are very frequently cured; when failure results the effort is to blame. Furthermore, we know that many tubercular foci in the bones can be made accessible to the surgeon and then cured by the removal of all the local disease. We know also that Nature often effects a cure, sometimes by a reactionary inflammation, which leads to the death of the germs and absorption of morbid tissues, and sometimes by, so to speak, organizing a sanitary cordon around the tubercular focus—*i. e.*, encapsulating it thoroughly. We must then study in what way we can either bring these foci of disease under the surgeon's hand, or else stimulate and compel Nature to assume a belligerent attitude against her unseen enemies.

And here we gather instruction from studying

[1] Holmes's System, 1883, vol. ii. p. 405.

[1] So far as I know, Prof. H. H. Smith, of Philadelphia, was among the first in *this* country to give prominent public expression to sound pathological views concerning tuberculosis of bone. *Vide* his address on Surgery and Anatomy, Transactions Amer. Med. Assoc., 1878.

what takes place under other circumstances. If I apprehend the general principles of surgical therapeutics aright, the surgeon never achieves so rapid and radical a cure of a chronic inflammation or its results as when he more or less completely replaces it by an acute one. Compare the radical treatment of hydrocele, which is certainly a chronic condition; whether the sac be emptied, or injected with carbolic acid, or be laid open by the bistoury, the result is the same—an acute inflammatory condition supersedes the chronic one, and recovery by obliteration of the sac follows. So in opening a joint for chronic hydrarthrosis, so in drilling or wiring bone for ununited fracture; so, too, in numerous other affections.

Inasmuch, however, as the balance of this paper is to be devoted to the discussion of a single therapeutic measure let me say here that I am in the fullest accord with, in the first place, the general principles of treatment by insuring physiological rest, constitutional remedies, etc., and in the second place with the plan of radical and early treatment of foci of softening, when recognized, by the knife, the curette, or the hammer and chisel; but since we can now often detect these forms of ostitis before they have caused such disorganization, we need especially to find some measure which shall lead, if possible, to resorption of those products of inflammation already present; and this measure I think we have found in that which for some time has been known abroad as *Ignipuncture*.

Ignipuncture simply means an application to the interior of the bone substance of the actual cautery in some form. It is unnecessary to stop here to describe how acute inflammation for a certain distance around must follow the application of the heated metal to any spot; the slightest experience with its use demonstrates that. On this principle is based the treatment by ignipuncture, and the success following it justifies its use.

It may be suggested that anything else which serves to set up a reactive and acute ostitis would be sufficient to cure a chronic form of the same, and this certainly is the case. Kocher, for instance, had a typical case of chronic ostitis of the head of the humerus which he treated by making an incision down on to the greater tuberosity, drilling the bone, and driving in an ivory peg. Examination six months after showed a good and actively movable arm, a joint almost perfect in its functions, and only a little fluctuating spot at the site of the operation. This was incised and the little ivory plug found almost in its integrity; the peg was removed, the incision readily healed, and perfect recovery followed.[1] With a view to setting up speedy reactive processes, Kocher and others have also drilled holes in diseased bone and filled them with strong tincture of iodine, and with good results.

But long before these observations Percival Pott had shown the value of deep-seated counter-irritation. He placed particular stress on the formation of issues extending deeply, and well knew their value in that form of caries of the vertebræ called by his name.[2] Much in the same direction was the much more recent effective, but clumsy effort of Fitzpatrick, who, in a case of tubercular caries of the hip-joint with great atrophy, made a *deep* issue with the caustic potassa fusa cum calce. By thus perforating the bone shell the softened tubercular *débris* was evacuated, and in seven weeks the contour of the limb was restored and the patient could walk.[1]

But these methods are all more severe than that now to be described. The actual cautery has been known from ancient times, and its use during the long centuries past has been at times quite wise, and at times quite otherwise.

Richet was among the first to make the cautery actually penetrate to the bone-marrow. His observations, which were never published in full, are best known to us through a brochure pertaining to the subject published by Juillard in 1874.[2] Juillard himself strongly recommends it, and devised a special galvano-cautery point for the purpose. Kocher, to whose casuistic I owe my first knowledge of the subject (*l. c.*), began its use independently of Richet's work, in 1872, perhaps even preceding him, and devised his own forms of cautery irons. Lücke began with the thermo-cautery, and this is the instrument now in use, so far as I know, wherever ignipuncture is practised.

In general terms we may hold that ignipuncture is indicated in all cases of chronic ostitis where fluctuation and sinuses or other indications of points of softening and breaking down do not call for the curette or chisel; and in many cases even after removal of products of softening the cautery can still be used to advantage to stimulate surrounding bone into a normal activity. Its application may be *intra-osteal* or *intracapsular*.[3]

If the former, the glowing platinum is either plunged through the skin and soft tissue right down to the bone and into its substance, or else an incision is made through a part or the whole of the soft parts since it is not so much disturbance of these latter which is primarily aimed at. Antiseptic precautions and dressings are of course indicated, and if the incision has been a large one it may be partially closed, but ample opportunity must be given for drainage so long as may be necessary. When combined with other operative measures a depot of softening may be cut down upon, its contents removed, the sharp spoon used as indicated, and from this bone cavity the cautery point may be made to perforate in different directions. The bone exposed to intensest heat is burnt into a crust; around this takes place an active inflammation which leads first to an osteo-porosis, and later to an osteo-sclerosis, which means virtual recovery. As I have already tried to show how often a primary bone lesion leads to a serious joint complication, it will be seen that the intraosteal ignipuncture may have a most important prophylactic effect as against the same; in fact, my own experience has taught me its value in this respect.

Intracapsular ignipuncture may be made either with or without previously opening the joint. If the joint

[3] Deutsche Chirurgie, Lfg. 19, 1880, p. 231.

is supposed to be in a fungous condition it should certainly be opened and cleaned out, but if it seems to be merely a lesion in a bone-end lying so close to the joint surface that it can only be approached by going through the joint, then no hesitation need be felt in burning right through the capsule and its cavity into the bone; only being doubly careful about the antiseptic precautions. Lücke does not hesitate to lay the joint freely open. If the joint surface is healthy and only bone is diseased, joint reaction is unlikely to occur. This measure is also said to be serviceable in chronic rheumatic and other forms of synovitis, though I have had no personal experience with it in such cases.

In every case in which I have resorted to it I have administered an anæsthetic, though Kocher states that he seldom gives one. The actual cautery used in this way and with the avowed purpose of securing, not a "derivative" effect, whatever that may be, but a speedy and acute reactionary inflammation, is to be considered quite apart from the vigorous counter-irritation which so many, like Syme for instance, have sought to induce by the moxa or any external application of cautery or issue. It has been, as stated, in use in a few of the foreign clinics for ten or twelve years. If it has ever with us been employed as *ignipuncture proper* previous to the time when I began using it late in 1882, the accounts of its use have never met my eyes; so that I am, as far as I now know, the first in this country, if not to try it, at least to make a practice of and recommend it. So far as my own experience goes, the first result of its use is a speedy relief of the characteristic ostitic pains; tenderness on pressure disappears later.

For the purpose of showing what the treatment is capable of accomplishing, I put on record the following cases selected from a not large but steadily increasing number of more or less similar ones recorded in my case-books.

Case I. was a most typical case of ostitis of the internal condyle. J. B., æt. twenty-one. Scrofulous diathesis. History of trouble dates back three months. Had been in a hospital a part of this time and under treatment by iced applications, rest, etc. He was admitted into the Michael Reese Hospital, Chicago, when I found on his admission marked enlargement of the internal condyle of the femur to such an extent as to deflect the leg notably to the outside of its proper angle with the thigh. It was extremely tender, gave him much pain, especially at night, and rendered the leg useless. Beyond a moderate effusion into the joint there was little or no joint affection proper. On February 23, 1883, I made a single ignipuncture, directing the cautery point into the centre of the area of tenderness, and burning in about 2 cm. ($\frac{4}{5}$ inch) below the bone surface. Iodoform dressings. All pain at once subsided. By April 9th the enlargement had disappeared, the leg resumed its normal position, and he could walk without pain. A week later he was discharged cured. During the months following I often met him on the street, and he always assured me of his perfect health.

Case II.—J. A., æt. fifteen. Scrofulous diathesis. Early in February, 1883, the patient took violent exercise while skating, was exposed in severe weather, and came home lame and tired out. This was the history I got when, a month later I took charge of his case and diagnosticated an acute osteomyelitis of both femurs, particularly of the left, with great sympathetic disturbance of both hip-joints. Indeed, so severe was the joint complication that the surgeon previously in attendance had lost sight of the primary cause and considered his case one simply of severe hip-joint disease. For a few weeks I kept him on supporting treatment, insured physiological rest by traction, employed counter-irritation—in a word, resorted to the routine treatment. All this time there was exquisite tenderness, of the left limb down nearly to the knee, of the right not so far, while suppuration had once or twice seemed imminent, and so widely were the bones affected that much of the bony pelvis was in the same condition. His sufferings were severe and called for anodynes.

Gaining at last the parents' consent, I had him removed to the Reese Hospital, where on May 3d I made ignipuncture by first incising down to the left trochanter major, and then burning into the upper end of the shaft of the femur and in the direction of the axis of its neck, going in fully 3 cm. ($1\frac{1}{5}$ inch). At the time of operating the bone could be felt to be fully a half thicker than its normal proportions, and in spite of the atrophy of the soft parts, which was considerable, the left thigh measured, near the pelvis, fully 2 cm. ($\frac{4}{5}$ inch) more in circumference than the other, while the bone of the other side was also thicker than it should have been. By May 5th he was free from pain except on the other side. By the 18th both thighs measured the same in circumference and he was quite comfortable. By the 28th the ostitis of the pelvic bones seemed to have nearly subsided save just at the pubis; he also complained of a painful and tender spot on the inner side of the left femur above the knee. So I again anæsthetized him and ignipunctured at the pubis, at the site of the first operation and just above the knee. Pain was again relieved. In three weeks he was up in a rolling chair; by the last of July he was around on crutches and could bear nearly his whole weight on his left limb; his joints were more or less stiff, but by passive motion he was daily regaining their flexibility.

Case III.—Lizzie F., æt. twenty-six. Patient has a marked family history of tubercular trouble; she has also had syphilis. In the spring of 1882 she had sacro-iliac disease on one side, for which she was kept in bed four months, with enough traction on the limb to enforce rest. By autumn she was in her usual health, except that she was troubled, as she had been for years, with leucorrhœa and with occasional muco-purulent discharges from the rectum; the rectal difficulty I considered to be an ulceration high up. For this last she had been under intermittent treatment, but her irregular and dissolute life prevented any systematic attempt to cure it. January, 1883, after a prolonged dissipation she had a relapse of the old sacro-illiac disease, and the trouble extended so as to involve more of the pelvis and the upper end of

the femur. At that time I diagnosticated tuberculous disease of the ilium, tuberosity of the ischium and femur. In spite of rest, anti-specific and supporting treatment and counter-irritation, her malady continued to aggravate, so that I finally suggested ignipuncture. In this advice my friend Dr. Ernst Schmidt, of Chicago, coincided; he having been cognizant of the results gained in Cases I. and II. above.

Therefore April 26, 1883, I chloroformed the patient, and after incising down to the bone I ignipunctured the trochanter major deeply and the posterior superior spine of the ilium less so. Iodoform dressings. This case, to our surprise, did badly. Within twenty-four hours she was irritable and irrational; on the third day she had lost all self-control, though her temperature was normal and the wounds in excellent condition. On the fourth day she was comatose, and from this coma she never aroused. Her temperature rose steadily, her respirations became more frequent until they were forty to the minute, with a pulse of one hundred and sixty, and she died on the eighth day with a temperature of 41.2° C. (106⅛° F.), respirations sixty-two, and pulse one hundred and sixty-five. Here was probably an acute general miliary tuberculosis with strongly marked meningeal implication. To my great regret, no autopsy was allowed. Whether tubercles were already deposited in the meninges, and the anæsthesia and operation together simply provoked a general eruption of tubercle already imminent, or whether my cautery point opened into a fresh mass of infectious granulations as well as into absorbents ready to sweep these fresh products into the general circulation, I cannot say. As between acute miliary infection as ordinarily known, or a fresh tubercle embolism corresponding to fat embolism, I could not positively decide. Either one or the other, perhaps both, must have taken place. Her family history, evident diathesis, specific disease, and dissolute life, were causes amply sufficient to make tenable either hypothesis. At all events, though this case was not a success, it did not shake my confidence in ignipuncture as a remedy and a prophylactic; it only made me wish I had used it much earlier.

Case IV.—Fanny H., æt. twenty-four. Tubercular diathesis. January, 1883, while menstruating for the first time in three months, she "caught cold," and the following day had a rigor followed by high fever and excruciating pain in her lower limbs. She gave in fact a typical history of acute osteomyelitis such as I have referred to briefly above, and which, as so often occurs, was not properly diagnosticated and treated. She was at that time in Minnesota and was treated for three months by her attendants for "rheumatism" before bone trouble was discovered. After she had been sick two months an abscess of the right thigh was opened, and has since continually discharged; another abscess on the thigh was opened, and then closed spontaneously. After some five months' illness she was brought to Chicago and placed in a private room at the Reese Hospital where, at request of Dr. Mannheimer, I first saw her.

June 1, 1883. *Status præsens:* General condition fair, except that she is very weak; bowels irregular; no menses since the time when she caught cold. She is helplessly confined in bed. Both femora enlarged throughout their entire length to the thickness of the middle of my forearm. Abscess on the outer side of right thigh discharging all the time. Inner condyle of right femur so enlarged as to throw the leg far out of its proper line, and, with the knees together, keep the feet at least twelve inches apart. Right knee quite stiff; very limited motion in left knee and both hips. Tissues all around the thighs and knees indurated and boggy. Pain continuous, but variable; anodynes in frequent requisition. In this case also I had the advantage of counsel with Drs. Schmidt and Mannheimer.

On June 9th I anæsthetized her and operated under the spray as follows: I made an incision on the outer aspect of the right thigh, some 25 cm. (10 inches) long, down to the bone, the periosteum being in some portions 2 cm. (⅘ inch) thick. There being considerable pus between the periosteum and bone, I made a counter-opening at the outer condyle, very near the joint cavity. The bone seemed so thoroughly disorganized and diseased that disarticulation at the hip appeared to be indicated, and would have been performed had the necessary consent been gained. A small incision was also made near the outer condyle of the left femur, where the same condition of affairs existed, only in milder degree. At this point I made a deep and large ignipuncture with the thermo-cautery.

Patient made an unexpectedly good recovery; pain vanished completely from the ignipunctured limb. In less than two months all discharge had ceased, and she was up in an invalid rolling chair and regaining considerable motion at the hips; the knees, however, were quite stiff. The femora were reduced to nearly their normal proportions. In this case an operation for the relief of anchylosis was made subsequently, and since leaving Chicago I have learned that she continued to improve so as to get around comfortably with a cane.

In this case I only ignipunctured one side; I should have done as much for the other, but at the time of operating the prospect of life of that limb, and even of the patient, seemed too hopeless to make it worth while. This case taught me an excellent lesson as to the viability of diseased bone.

Case V.—J. H., of Pennsylvania, æt. forty. In 1875 patient had an ischio-rectal abscess which broke spontaneously, and established a fistula in ano that still persists. I mention this here to show the concurrence of two tuberculous lesions, apparently local and independent. In November, 1879, he "turned the left ankle under him," doing such damage that his medical attendant told him he had broken some bone; which one he does not know. Not long after this the lower end of the tibia began to enlarge; a sinus opened, discharged a year, and then closed. By May, 1880, he was able to move about with a cane, but in May, 1883, it became worse, so that he could scarcely bear his weight on it for more than an hour.

December 1, 1883, he was admitted under my

care in the Buffalo General Hospital. *Status præsens:* A large, well-nourished frame; general condition fair. Fistula in ano present. Find also the lower end of the left tibia much enlarged and club-shaped; notable atrophy of soft parts above and below; motion at ankle barely possible; extreme tenderness about internal malleolus, and on pressing the foot against the tibia. Complains of pain, worse at night. Diagnosticated ostitis tuberculosa.

December 12th, in my clinic, I anæsthetized him, and making an incision down to the periosteum at the internal malleolus, I first explored with a bone drill to see if I might find any pus. Finding none, I ignipunctured in different directions with the thermo-cautery point, going in fully 2 cm. ($\frac{4}{5}$ inch). Naphthalin dressing. At the same time I operated on the anal fistula, and scraped out a quantity of detritus such as I have already spoken of as tuberculous.

Within ten days the bony enlargement was perceptibly smaller, and most of the tenderness disappeared. Pain was relieved at once. The joint also could be moved almost to its full extent. On January 23, 1884, there being still a point of considerable tenderness, I repeated the ignipuncture. By March 1st the bone had resumed its natural size and shape, as compared with the other side, and he could bear nearly his whole weight on the foot. He made an excellent recovery.

CASE VI.—Ethel S., æt. five. Deaf-mute. Tuberculous diathesis and family history. Patient brought to me from Canada. When sixteen months old she spontaneously developed a disease of the left knee, and for some months would not use it. After a while it straightened out from its previously flexed position, and she began to use it again. December 15, 1883. *Status præsens:* Typical tumor albus, with contracture to a right angle; subluxation backwards of head of tibia; clubbing of lower end of femur; atrophy of soft parts, and moderately firm anchylosis. In my clinic on that date I made tenotomy of hamstring muscles and lateral ligaments, and then applied traction with hot fomentations about the knee. Within a week the limb was very nearly straight. At this time the circumference of the knee-joint was four centimetres greater than that of the other knee, in spite of great atrophy of soft parts.

January 9, 1884, there being a point of great tenderness over the internal condyle, as nearly as could be made out from the actions of the child, I ignipunctured through the capsule. The child went home February 16th with a joint movable through an arc of 100 degrees, only *1 cm.* ($\frac{4}{10}$ inch) of difference in circumference as between the two knees; no signs of special tenderness could be elicited. A posterior straight splint, with daily passive motion, and a high shoe sole on the other foot with the use of crutches, were advised. August 1, the limb is in a most satisfactory condition.

I will not now add to the number of these cases, for I think they serve as well as would twice their number to demonstrate what ignipuncture may be expected to effect. I have not yet seen fit to resort to it in incipient spinal caries, in which cases I, at the same time, think it would be of marked benefit. The deep position of the bones affected, and the somewhat extensive operation necessary to expose them for this treatment, have so far deterred me from attempting it; but the more I extend my experience with it the more I feel that the experiment should be made. Nor am I aware that anyone else has seen fit thus to use it. But for all accessible bone disease of the kind I have described I cannot but feel that we have here a procedure which is both curative of the present disease and prophylactic against extension; and that its extension may be the cause of frightful local ravages, not to say of acute general miliary tuberculosis, a study both of cases and of recent literature will fully convince.

305 DELAWARE AVENUE,
BUFFALO, N. Y.

URTICARIA AS A CAUSE OF MISCARRIAGE.

BY S. J. RADCLIFFE, AM., MD.,
OF WASHINGTON, D. C.

OF all the reflex causes of premature birth, or miscarriage, I have seen none attributed to urticaria. Excessive irritation of the nervous arcs—mammary, rectal, or uterine—or of the periphery, or of any of the internal organs, especially excessive gastric or intestinal irritation, as from dyspepsia, diarrhœa, dysentery, or intestinal worms, are spoken of as probable causes of abortion or premature birth; but general febrile diseases, smallpox, and other exanthemata, as scarlatina, and relapsing fever even, seem to have no particular or immediate effect in that direction, even should the fœtus or child in utero be attacked simultaneously with, or consecutively to, the mother, which is known to be the case—the child being born with pustules of variola on some portions of the body, or shows signs of other eruptive fevers, as scarlatina. If miscarriage or abortion should occur from such causes, as they do sometimes, a fatal issue is apt to be the result. Dr. Charles A. Leale reported a very interesting case, in a paper read before the New York County Medical Association, April 21, 1884 (THE MEDICAL NEWS, May 31, 1884), of scarlet fever in a child at birth, the mother being at the end of the ninth month of pregnancy, labor being induced when she was in the early part of the eruptive stage of the fever. The child was delivered with the forceps, and was also in the eruptive period, simultaneously with the mother. This only shows, however, that scarlet fever does occur at such periods, and may occur at any other, but not that it produced premature delivery, though it possibly hurried delivery in this case.

The ordinary accompaniments of pregnancy have usually no deleterious effect on its progress. Leishman says: "In so far as the familiar affections which so frequently attend early pregnancy are concerned—such as sickness, faintness, salivation, and the like—and which, when extreme, are considered among the diseases of pregnancy, it has always been observed that these are very rarely the cause of abortion. The most common of all—sickness—is, even in the worst cases, little liable to be followed by premature expulsion. 'It is,' as Dewees says, 'a re-

mark as familiar as it is well grounded, that *very sick women rarely miscarry.*'" These affections continue frequently up to the end, and only cease with a natural and easy delivery, or the child may have even gone through an eruptive disease, the mother being a mere conductor of the contagious principle, without miscarriage. "As an illustration of which, in the case of smallpox," Leishman says, "Mauriceau tells us that shortly before he was born, his mother had the misfortune to lose the eldest of her three sons by this disease, and that, in spite of her condition, as women will do, she tended him with constant and tender care. Mauriceau was born the day after his brother's death, and, although his mother neither then nor subsequently presented the slightest symptoms of the disease, he had on his body at his birth five or six undoubted variolous pustules."

The local causes of abortion and premature birth are various. Hart and Barbour (*Manual of Gynecology*) say: "The cause of abortion may be (1) in the fœtus, or (2) in the mother. On the part of the *fœtus*, disease of the chorion and hemorrhage into the fœtal part of the placenta produce death of the fœtus and consequent abortion; these conditions are most frequently due to syphilis. On the part of the *mother*, endometritis and metritis are the most important causes. General debility and fevers (typhus and scarlet) also produce abortion." And also "it is evident that a severe blow or fall might lead to hemorrhage and separation of the membranes," and consequently miscarriage.

Leishman says: "Many of the causes which have been enumerated as inducing abortion may also operate similarly at this more advanced period of pregnancy, but there are undoubtedly other special causes which may also be mentioned. The most important of these latter is over-distention of the womb, from whatever cause this may arise. Plural pregnancy, dropsy of the amnion, and hydrorrhœa, are all causes of this nature; and the immediate result of their operation is that the uterus attains, at a period much earlier than is usual or normal, that degree of distention which is characteristic of completed gestation."

A little review of the definition, etiology, and pathology of urticaria may give some insight into the reason why it might play so important a part, in causing the premature expulsion of the contents of the womb, an action which can only be looked upon, probably, as entirely reflex in its nature.

Plumbe and Hillan place urticaria among the exanthemata. McCall Anderson places it among the inflammations, with erythema, eczema dermatitis, and erysipelas. Dr. George Henry Fox also classifies it under the head of the inflammatory affections with eczema dermatitis, etc., and so do most all dermatologists.

Plumbe says: "Urticaria has constitutional causes, and is allied to prurigo, and consists chiefly of that species of determination to the skin, produced by sympathy with the stomach, or by local irritation." Wilson Fox says "it complicates acute catarrh of the stomach, and is often caused by shell-fish, mushrooms, cucumbers, etc., or by substances against which the patient has a special idiosyncrasy."

Niemeyer says: Urticaria has been classified according to the different exciting agents which produce it: "1, from external irritation; 2, from ingesta; 3, urticaria febrilis; 4, chronic urticaria; 5, there is a form of urticaria mentioned by Hebra which is evidently dependent upon uterine irritation, and which appears in some women during pregnancy, in others during menstruation, while in others again it accompanies diseases of the womb, or follows the introduction of pessaries."

The pathological conditions entering into this form of disease are not easily settled. Like many other affections, it has not been decided whether it is a purely local affair as a dermatitis *per se*, or a general febrile or blood disease, as erysipelas, etc., the external appearances being only symptoms of a deeper trouble, or a simple neurosis. Authorities differ as to all of these views. The generally accepted opinion is that it is a local irritation or dermoid inflammation, according to Niemeyer, in which a serous infiltration of the papilla of the skin, and probably, too, a swelling and infiltration of the cells of the rete Malpighii cause the formation of circumscribed flattened elevations, whose width is greater than their height, and which are called wheals, dependent partly upon external causes, but principally upon altered fluids or retained excreta, absorbed into the circulation, from unwholesome ingesta; such fluids or poisons being noxious to certain cell elements, cause the changes which take place in the skin, and the great discomfort so characteristic of the disease.

In this view of the pathology of urticaria, it is a fair question to ask whether the unwholesome ingesta were the prime factor, and the dermatitis the secondary effect, and, whether the deleterious matter operated through the general circulation or through the nerve-centres.

Handfield Jones says: "Urticaria, by its fugitive character, by its manifold and various causes, by its nocturnal invasion, by the dysæsthesia attending it, and by the nature of its phenomena, fully asserts its title to be regarded as a neurosis. . . . It is, I think, probable that the dysæsthesia and the cutaneous contraction are co-results of the same nerve disorder, and that the latter is not merely the reflex of the former. The spasm is certainly not dependent upon hyperæmia, as in urticaria evanida it occurs without any. The diffuse inflammatory redness of the skin, which is marked in some instances, and attended even with swelling, must be considered as an indication of vaso-motor nerve paresis, and we thus get in this curious malady three different pathological changes, resulting from the operation of the same cause, viz., spasm of contractile tissue in certain parts, paralysis in others, and a state of hyper- and dysæsthesia of sensory nerves." "Like most neuroses, urticaria may be produced by remote irritation, which is in many cases seated in the intestines, but may be elsewhere, as in the female sexual organs." Charcot mentions particularly cutaneous affections accompanying nerve disorders, and says: "In the case of a woman at present under treatment at La Salpêtrière (for locomotor ataxia), enormous patches of urticaria are produced at every paroxysm on the

parts where the keenest pains are felt. (*Lectures on Nervous Diseases;* Philadelphia, 1879.)

References might be multiplied to show that this is the correct aspect of the subject, and why it might be a prime element in the causation of miscarriage. Viewed as a neurosis, very much of the effects of urticaria might be accounted for, especially when we regard the intense systemic irritation it produces, and the manifold secondary complications it is liable to engender. It is in this point of view that I have regarded the subject, and in which I present it. The following case I report as bearing somewhat upon the matter, and hope it will not be without interest:

Mrs. ———, aged twenty-six, native of Virginia, strong, healthy woman, mother of one child two and a half years old, pregnant for the third time, in the eighth month of utero-gestation; miscarried October, 1881, at third month, supposed from abdominal pressure, from carrying her child on one arm and a heavily filled market basket on the other. Had much hemorrhage, and was very much reduced. Was attacked the morning of 22d July, 1882, with severe lancinating pains about the umbilicus, attended by much nausea, and incessant vomiting of large quantities of clear greenish fluid, which came up without effort, as if by mere contraction of the stomach. Her body, from head to foot, was thickly covered over with the eruption of urticaria, particularly over the abdomen and face, the face being intensely red and puffed, and with it distracting burning and itching. Her pulse and temperature were considerably increased, bowels slightly constipated, and tongue lightly furred. She did not remember to have eaten anything to disagree with her; had rather been abstemious; but, remembering her miscarriage only nine months before, had been greatly concerned for some time about her condition, much more so than usual, for fear something should happen to her for evil, either before or during her confinement. This thought had kept her in a nervous state, and this sickness coming on her suddenly, almost without premonition, still further alarmed her. I prescribed rest and an alkaline and opiate mixture, and afterwards a saline aperient when the pains had subsided. The pain and vomiting ceased after a few doses of the medicine. The aperient gave her two light operations in the morning.

23d.—11 A. M. she was free from pain and sickness of stomach, and the urticaria had partially faded, but was yet visible over most of the body, and still caused much distress. She felt better, and desired to get up. She said she had not felt the fœtus move since the 22d, the day she was taken sick.

24th.—At 4 A. M. was called in haste, and on my arrival found she had miscarried of a well-formed, full-sized, stillborn female child, of the eighth month. The placenta was detached, and was easily removed. The urticaria at once began to disappear, and in three or four days was entirely gone, and she made a good recovery.

July 18, 1883.—She was delivered of a full-sized male child at term, with no return of the urticaria.

1211 F Street, N. W.

REPORT OF A REMARKABLE CASE OF COUGH.

By ALEXANDER W. MacCOY, M.D.,
MEMBER OF THE PHILADELPHIA LARYNGOLOGICAL SOCIETY.

The following is a report of a case under my care for some time, sent to me by a prominent practitioner of this city, who desired me to take charge of the case, and determine if anything could be done for her relief.

Mrs. S., æt. 40, resident of Philadelphia, married twice, the mother of one healthy child, was first seen in December, 1882. At this time she was suffering from an almost continuous, exhausting, irritative cough, accompanied by violent fits of gagging which had defied all treatment, and which had continued for several years. The patient was very thin of flesh, and her face much careworn. She stated that her attacks of cough often lasted for hours, and were frequently accompanied by the fits of gagging, which came on after the cough had continued for a short time. Sometimes after ascending the stairs, gagging would follow and soon render her helpless. Her debility was so marked after one of these paroxysms that she frequently had to go to bed, and was compelled to remain there for some hours. Between the attacks of coughing and gagging she was rendered most miserable, and was completely debarred from social engagements.

Examination showed no pulmonary disease. Inspection of fauces revealed marked cicatrices involving most of the posterior pharyngeal wall, extending well down the throat. Laryngoscopic examination at once made manifest the cause of her attacks. On a line with the superior margin of the arytenoidal portion of the larynx, on the posterior wall of the pharynx, was a horizontal cicatricial band extending well across the pharynx about one-eighth of an inch in diameter, the ends of which spread out in a fan-shaped manner, the fibres being lost in the tissues on each side. This band was so placed that the free edge of the epiglottis was touched by it while rising and falling, and readily explained the cause of the cough. The gagging was brought about by interference with the free action of the vertical and circular muscular fibres of the pharynx, as well as by impingement of the free edge of the epiglottis.

The *specific* action (undoubtedly the cause of the destructive change) had long since ceased. While there was no direct history of syphilis, there was a history of a severe attack of ulcerative disease many years before, which she states her physician called diphtheria. No lesions of syphilis excepting those found in the throat were visible.

The treatment consisted in dividing the cicatricial band with the galvano-cautery knife *vertically*, and dilatation. The first operation was not attended by perfect success, owing to the incision being too near the median line. A few weeks after the first operation a second incision was made on the left side much longer and deeper than the first one. This effort was eminently successful. For six months there was absolutely no return of cough and gagging. Quite recently there has been some return of her

attacks from neglect to keep up the dilatation. Another operation of multiple incisions was made a few months ago, which again completely relieved her. With occasional dilatation it is probable that the result will be perfect, but without it contraction will certainly occur in time (as is so well known), and the result will not be so satisfactory as it now is.

The adaptability of the galvano-cautery knife for the relief of this condition has so impressed me that I am unable to see how the operation could have been performed so safely and so well by any other method.

1417 WALNUT STREET.

MEDICAL PROGRESS.

PASTEUR'S EXPERIMENTS ON HYDROPHOBIA.—M. PASTEUR, in his address before the International Medical Congress, related the latest results of his experiments concerning (1) trephining; (2) injection into the blood; and (3) the bite of the dog. When he had discovered his method of inoculating dogs, and so made many dogs insusceptible of hydrophobia, he requested the French Government to appoint a competent committee to judge of his results. The request was granted by the Minister of Education, M. Fallières, who appointed MM. Béclard, Paul Bert, Bouley, Tisserane, Villemin, and Vulpian, as members of the Committee. This Committee has just sent its report to the Minister, of which the following are the most important points. M. Pasteur gave twenty-three inoculated dogs to the Committee. These were compared with nineteen non-inoculated dogs selected by the Committee. The Commission first observed that, in guinea-pigs, the onset of hydrophobia occurred five days after inoculation, and it was also ascertained that, in rabbits and dogs, the period of incubation was extended to twelve or fifteen days. The experiments, by the request of the Commission, commenced by inoculations made within the cranium. The matter for inoculation was taken from the pons Varolii of a dog who died in the infirmary at Alfort, from ordinary hydrophobia. A circular piece of bone, five or six millimetres in diameter, was removed with the trepan, and the inoculation was made with a syringe in which the extremity of the needles was bent almost to a right angle, so that the matter was inoculated immediately beneath the dura mater, and not into the cerebral substance. In this manner, two dogs who had been submitted to prophylactic inoculation, and two who had not, as well as two unprotected rabbits, were inoculated; subsequently, two protected and two unprotected dogs were allowed to be bitten by a dog suffering from hydrophobia; and after the death of this dog, six other dogs, three protected and three unprotected, were inoculated. On subsequent days, the experiments were repeated and varied. Altogether, forty-two dogs were used, of which twenty-three were protected by prophylactic inoculation, and nineteen were unprotected. Of the nineteen not protected, fourteen died of hydrophobia; that is to say, of animals bitten, three out of six died; of eight animals in which intravenous inoculation was performed, six died, and all five inoculated through an aperture made in the cranium with a trepan; of the twenty-three dogs protected by prophylactic inoculation, not one died of hydrophobia, one died with diarrhœa; but inoculation showed that there was no reason to suppose that the animal had hydrophobia. The work of the Commission is for the present arrested, but will be resumed; attention will be particularly directed to the methods of vaccination, and to the question whether the inoculation of an animal already bitten can prevent the subsequent development of the disease. M. Bouley, writing in the name of the Commission, testified that, so far as the investigation had gone, it had been found that M. Pasteur had advanced no statement which was not rigorously exact. He had established that, by inoculation with an attenuated virus, dogs could be rendered refractory to hydrophobia. It yet remained to be ascertained for how long this immunity persisted. The Commission now intends to vaccinate twenty dogs of their own accord, so as to ascertain results independently of M. Pasteur. M. Pasteur finished his address by stating that animals are proportionately less infected by bites from dogs than by inoculation. His experiments had only produced results with regard to animals, but he considered it most likely that, if the dog could thus be made insusceptible of hydrophobia, the source of this dreadful disease in man would be extirpated, and the question as to prophylaxis, both for dog and man, would be solved.—*British Medical Journal*, August 16, 1884.

INTESTINAL RESECTION AND SUTURE.—FIELD reports (*Arch. f. klin. Chir.*, Bd. xxx. S. 222) the case of a man, æt. 33 years, who came to the Clinic at Bonn with a strangulated hernia four days old. The hernia was gangrenous, and Field resected four inches on the concave side of the intestine, and four and a half inches on the convex side; and put in sixteen fine, and twelve deep sutures. A fine needle, and the finest sort of silk were used. Although it was necessary to reopen the wound, and though the patient had an attack of pneumonia during convalescence, he was well in six weeks after the operation.—*Centralbl. f. d. med. Wissensch.*, July 12, 1884.

REMOVAL OF GALL-STONE FROM THE ILEUM.—Dr. J. M. Browne, U. S. N., reports a case which occurred in the practice of DR. WM. E. TAYLOR, U. S. N. (retired). The patient was a woman, about forty-five (?) years of age, who had abdominal pain and nausea, no action from the bowels for two days, and enemata and laxatives had failed. Nothing wrong was found at any of the usual hernial outlets; the rectum was empty, and the uterus normal and in good position. There was but little tenderness, and no apparent swelling; excessive fat made an abdominal diagnosis difficult. Dr. Taylor was most impressed as to the serious nature of the case by the "shock" and increased frequency of the pulse, which he has always seen in gut-injuries, whether from wounds or strangulation. The vomiting, which had been bilious, became stercoraceous. Under the belief that there was an acute obstruction, an operation was performed. A band surrounding the ileum was encountered and divided, and, following the distended gut down, a hard, pear-shaped body was found firmly impacted in the ileum, at its lower portion, say, some twelve or eighteen inches from its lower end. This

body was situated with its small end pointing downwards, and fitted as tight as a cork, not even allowing wind to pass it. It could not be moved, nor could the fingers make any impression on it, by any *safe* pressure. A needle was introduced through the wall of the gut, but it was too hard to be broken. The intestine was opened by an incision one inch in length, and the gall-stone removed; the wound in the gut was sewed up and the abdominal wound carefully closed.

The patient died on the fifth day. At the autopsy the gall-bladder was found thickened and closely adherent to the duodenum, with an opening nearly an inch in diameter leading through into the bowel, the peritoneal cavity being shut off by the adhesions. The intestinal wound was so far healed as to prevent the escape of contents. There was but little more peritonitis than at the time of the operation. The wound in the abdomen had not taken on much repair. The stone was pear-shaped, nearly two inches long, and one inch in diameter. —*Proc. Naval Med. Society*, vol. ii. No. 1.

Alterations of the Kidneys from Uterine Fibroids.—Prof. S. Pozzi, at the close of an article on this subject, draws the following conclusions:

1. Compression of the bladder and ureters is a frequent complication of fibroid tumors of the uterus, even when they are of moderate size; and they may rapidly cause grave kidney lesions, such as hydronephrosis, cysts, sclerosis, and fatty degeneration.

2. When the compression acts directly on the bladder, it is easily recognized. When, however, the ureters are compressed, the trouble may not be recognized until kidney lesions have been produced, and variations in the urine from the normal (as albuminuria) detected.

3. Compression of the bladder or ureters should be of great weight in determining an operation (hysterectomy), and are alone sufficient to cause a hasty intervention on the part of the surgeon.

4. In case of hydronephrosis, the indication for operating is particularly pressing, in view of the danger threatening the kidney. The treatment of these complex cases may be rendered less grave by first performing hysterectomy, and, after the patient rallies from this, then attacking the cyst.

5. The prognosis of hysterectomy is considerably graver when an examination of the urine shows renal alterations; and should they be very advanced, as in confirmed Bright's disease, the operation is contraindicated; a moderate amount of albuminuria, however, is not a contraindication.—*Annales de Gynécol.*, July, 1884.

Swollen Axis-cylinders in the Cord.—Fr. Schultze reports (*Neurologisches Centralbl.*, No. 9, 1884) the results of the examinations of the spinal cords from six cases of parenchymatous, and three of interstitial nephritis. In three cases he found the axis-cylinders swollen, especially in the dorsal portion and in the lower portion of the cervical enlargement, and for the most part in the periphery of the lateral columns (Seitenstränge). There was no meningitis in the doubtful cases. Œdema and dropsy seemed to play no part in the origin of the swelling, since it was found to an extraordinary degree in a case of leukæmia in which there was no œdema at all. It appears to be due to altered nutrition of the axis-cylinder, caused by general alterations in the quality of the blood.—*Centralbl. für klin. Med.*, July 26, 1884.

The Condition of the Axis-cylinders in Multiple Sclerosis.—In a case of multiple sclerosis of the spinal cord (extensive, diffuse, irregular chronic myelitis) Schultze found the pyramidal tracts of the cervical portion, together with the greater part of the anterior and lateral columns, altered, and also the whole posterior columnar region in the lower cervical portion. Still, there was not the slightest secondary degeneration of the lateral columns of the dorsal portion, corresponding to the posterior columns of the cervical portion of the cord. As is known, the absence of secondary ascending and descending degeneration in multiple sclerosis is the rule, and it is a question how this apparently anomalous condition is to be explained. Charcot has already shown that the axis-cylinders exist in a certain quantity in the central regions of the sclerosed masses; and Schultze proved this very satisfactorily by Freud's gold-chloride method. They were completely without nerve-pulp, and partly swollen. From this it appears that the absence of secondary degeneration requires an extensive alteration of the axis-cylinder, and is not due to complete loss of the pulp-sheath to a circumscribed extension upwards.—*Centralbl. f. klin. Chir.*, July 26, 1884.

The Alexander-Adams' Operation for Displacement of the Uterus.—Mr. Robert Miller reports two cases operated on at the Town's Hospital, Glasgow. The operation consists in making a simple skin incision over the external inguinal ring, gathering up the ends of the round ligaments and drawing them sufficiently out to restore the womb to its normal position. Finally, the ends of the ligaments are stitched to the edges of the wounds.

Both the cases operated upon were successful. Dr. Adams, in commenting upon them, says that these cases show the immediate relief that may be obtained from this operation in cases of *prolapse*. There is, however, some risk of the operation becoming discredited from two causes. Thus it requires considerable experience to recognize, catch up, and manipulate properly the ends of the ligaments. The least rough handling may tear them, and too much poking within the wound by unskilful exploration is apt to produce a condition favorable to hernia, and favorable to the induction of suppurative action. Then in cases of old retroversions or flexions, in which the posterior portion of the fundus uteri has become more or less hypertrophied, the operation will only yield partial *immediate* relief, and it is through time alone that the altered circulation will affect the dense uterine tissue, and alter for the better the nutrition of the organ. That it does do so is shown in one case in which menstruation has been reëstablished after a long lapse of years.

It is better to cut off about one inch of the ligament, as the extremity usually sloughs. The manipulation required even in experienced hands is an obstacle to the chances of getting the wound to heal by first intention; but with more frequent opportunity I am becoming sure that this may be obtained in the majority of cases. The catgut used should be prepared to with-

stand the action of the tissues for ten days; and in addition to stitching the ligaments to the pillars of the ring, the sutures bringing the external wounds together should pass through the ligamentous tissue that projects from the ring.—*Glasgow Medical Journal*, August, 1884.

Neutral Sulphate of Atropine in Acute Otitis of Children.—Since Dr. Gentilhomme made known about two years ago the good results obtained by the administration of atropine for catarrhal inflammations of the nose, several confirmatory observations have been published. The action of atropine is undoubtedly favorable in the greater number of cases; in some cases it is so energetic, even in doses of gr. $\frac{1}{150}$, that considerable dryness of the pharynx is caused, and deglutition rendered so difficult that the patient cannot swallow solids. These effects are particularly intense in patients who have a commencing pharyngitis sicca.

Dr. C. Miot has prescribed the solution of atropine for a certain number of children who were often affected with intense rhinitis, and had, at the same time, an acute otitis on one side or the other. The atropine aborted the rhinitis and prevented the otitis. Miot has notes of over thirty cases in which this treatment was successful.—*Rev. de Laryngol, Otol., et de Rhinol.*, Aug. 1884.

Cystoid Degeneration of the Arachnoid.—Prof. Langerhans, in his *Inaugural Dissertation*, Berlin, 1884, describes four cases of cystic degeneration of the arachnoid, with marked anomalies of the brain, which were observed during the first half of the semester of 1883–84 in the Pathological Institute in Berlin. In the first case there were multiple defects of the cerebral hemispheres; in the second, there was a cyst as large as a hen's egg in the cerebellum; in the third, there was a cyst at the base of the left parietal lobule as large as a pigeon's egg; and in the fourth case, there was a cyst at the apex of the left parietal lobule as large as a pigeon's egg. These cases are interesting from the fact that none of them presented any clinical symptoms of brain tumors during life.—*Centralbl. f. d. med. Wissensch.*, July 12, 1884.

Splenectomy.—Dr. Koeberlé recently related, to the Société Médicale de Strasbourg, his second case of splenotomy, performed on a woman, forty-six years old, for a hypertrophied spleen, the result of intermittent fever. Both this and his first case were examples of the largest spleens that had ever been removed, the organ in both cases resting on the pubis, while there was also great enlargement of the liver. The spleen in the present case measured 40 cm. (16 inches) in length, being only 5 cm. (2 inches) less than in the other case, in which the organ, when emptied of its blood, weighed over 17 pounds. The affection had run a rapid course of less than a year and a half, and at last there was effusion into the pleura, pericardium and peritoneum, the patient being much emaciated and cachectic, passing but a small quantity of urine and exhibiting a temperature of from 102° to 104° F. As in the former case, there was great adhesion to the diaphragm. In that case fatal hemorrhage had taken place from the vessels of the adhesions, but in the present case this was prevented by three ligatures on the splenic vessels. As a consequence of the constriction caused by these, arterial hemorrhage took place from a large number of cutaneous vessels along the line of incision, where complete hemostasis had prevailed for more than an hour. A great deal of blood (which was very plastic and rich in coagulable fibrin) was in this way lost; but in spite of this the patient rallied well for a while after the operation, which lasted nearly three hours; but in about an hour after its completion she was seized with convulsions and died. This case is another example of the danger of removing large spleens; but the operation was only performed at the woman's insistance, after its danger had been completely explained to her.—*Med. Times and Gaz.*, August 2, 1884.

The Functions of the Phrenic Nerve.—J. Schreiber (*Pflüger's Archiv*, Bd. xxxi. S. 577) states that in narcotized and curarized dogs, the mechanical and electrical irritation of the central end of the phrenic nerve, in the region of the trunk and roots, is succeeded by a slight, but nevertheless noticeable, rise of blood-pressure. After section of the roots, from the fifth and sixth cervical nerves, irritation of the trunk caused no increase of blood-pressure. The upper root was shown to be powerless, whilst the trunk reacted.—*Centralbl. f. d. med. Wissensch.*, July 26, 1884.

The Pharmacology of Cantharidin.—Dr. Evgeny A. Liakhnitzky has recently made some extensive researches on this subject (*St. Petersburg Dissertation*, 1884). Frogs, dogs, and rabbits, into which he introduced cantharidin and cantharidate of soda, were used for his experiments. He sums up the results of his nearly two years' investigations as follows: 1. The physiological action of cantharidate of soda (natrium cantharidinicum) is identical with that of cantharidin. 2. Canthardin (and cantharidate of soda) produces an increase in frequency of the heart's action, in consequence of paralysis of the vagus. 3. It does not display any strongly manifested influence on the arterial tension, since the latter is lowered only under toxic doses, in the period before death, and then mainly in consequence of a growing weakness of the cardiac muscle. 4. It causes a retardation of respiration in cold-blooded animals from the very beginning, and in the warm-blooded after a preceding acceleration, the phenomenon being dependent upon the weakening of the respiratory centre. 5. It does not change the excitability of muscles or of the motor and sensory nerves. 6. In cold-blooded animals there is observed a loss of reflexes, which depends mainly upon the lesion of reflex centres in the spinal cord. 7. The main ways of elimination of cantharidin out of the system are the kidneys, the intestines, and the salivary glands. 8. On its being introduced into the blood, cantharidin is found almost in all organs of the body, but the greatest quantities are detected in the liver, kidneys, salivary glands, and gray matter of the brain. 9. The lesions of the bowels, which occur even on extravenous injections, present one of the most marked symptoms of poisoning by cantharidin. These lesions are caused by secretions of cantharidin by the intestinal mucous membrane. 10. Cantharidin produces slight oscillations of the temperature, in general tending to lowering the latter—*London Med. Record*, July, 1884.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, AUGUST 30, 1884.

THE CHOLERA.

THE outlook in France, Italy, and Switzerland is not so good as it was a week ago, and the late increase of cholera at Toulon would seem to indicate that the disease has lost none of its force in the quarter where it first made its appearance, over two months since. Its gradual spread throughout southern and eastern France, crossing the Alps and invading Italy and Switzerland on the one hand, and stretching westward to the Bay of Biscay on the other, would lead us to fear that the prophecy of Professor Koch may yet be verified, that all Europe will suffer with the scourge before it takes its final departure.

In our own country, we have so far been very fortunate, escaping both yellow fever and cholera, though more than once threatened by yellow fever ships, and at least once by a cholera-infected vessel.

The vaunted "sanitary precautions" suggested as a preventive of cholera, and inaugurated in many of the villages of France, have, it is stated, proved ineffectual in staying the progress of the disease. Whether this be true or not, we cannot afford to relax our own efforts in this direction, and we believe it is incumbent upon all our health authorities, municipal, state, and governmental, to continue the work of keeping our cities and our shipping clean.

We may escape this year, the probabilities now are that we will, but the past history of this disease warns us that so long as it is in Europe we are in danger, and that winter is no certain safeguard against its progress; therefore, it behooves us to keep up the fight against filth in every form, and leave no place for the disease to obtain a footing.

FAT EMBOLISM.

THE subject of fat embolism can hardly be said to have received its proper recognition by the surgeon, whom, of all medical men, it chiefly concerns. For although the condition would seem to be one of the possible consequences of the lipæmia of diabetes mellitus, yet in this affection it is doubtful whether it adds much to the existing dangers of the disease at the stage when it may supervene, while it would seem to be due rather to the fusion of numerous small globules of oil, and sometimes, at least, to be mistaken for the post-mortem coagulation of a blood highly charged with fat. In no other medical affections are we aware of its having been noted.

In cases of injury opening the medullary canal of bones it is an ever-present danger, and, although our resources for its prevention are as yet extremely limited, it is hardly likely that they will be increased until we thoroughly recognize the probability and symptoms of its occurrence.

The condition, at least as the result of injury, appears to have been first discovered by Zenker in 1862, although two years earlier Müller noted that the choroid vessels of a patient were filled with liquid fat, which he supposed to have come from an atheromatous aorta. Since then it has been studied by others, and especially by Wagner in 1862, Bergmann in 1863, Schwick in 1864, Wagner and Uffelmann in 1865, Pellis, Busch, and Buttlewsi in 1866, Niederstadt in 1869, Fitz in 1876, Flournoy in 1878, Egli-Sinclair, Déjérine, Scriba, Wiener, and Fenger in 1879, Saundby and Barling in 1882, Pinner in 1883, Vogt and Bardeleben in 1884, and most recently by DR. ROSWELL PARK in the *New York Medical Journal*, who furnishes an excellent historical *résumé* of the subject, discussing also the etiology, pathology, and symptomatology.

The following illustrate the phenomena of the condition: In eight cases studied by Saundby and Barling, in which there was severe injury, which none of the victims survived more than five days, fat emboli were found in the lungs. In a ninth case, which suggested the study of the others, a compound comminuted fracture of one leg had been sustained, and a long interval had elapsed before surgical treatment was applied. On the second day, the pulse, temperature, and respiration having all been increased, the patient, without any other premonitory signs, became semi-comatose, the face flushed, and the breathing stertorous. Subsequently there was marked cyanosis. These symptoms continued until death supervened, three days after the injury. After death the microscope revealed numerous emboli in the small arterioles of the lungs, and a few in the capillaries; emboli were also found in the vessels of the glomeruli of the kidneys. In none of the other cases did any

symptoms suggest the presence of the condition, but the degree of embolism, also in the lungs, was very much less.

In two cases of sudden death succeeding fracture of the humerus and neck of the femur, which occurred in men twenty-seven and twenty-eight years of age, under Bardeleben's care, fat embolism was found in the lungs. In both cases death occurred at the beginning of chloroform narcosis, and there seemed to be no disposition on the part of those reporting to ascribe death, in either case, to the anæsthetic. (*Centralbl. für die med. Wiss.*, March 8.) In another case, under Vogt (*Ibid.*), death occurred in a girl twelve years old, twenty-four hours after resection of the knee on account of fungous disease, and was ascribed to the same cause. The surgeon thought that the liquid fat which exuded abundantly from the cut surfaces of the bone was absorbed.

In our issue for May 19, 1883, we called attention to a case of fat embolism reported by PINNER, in which there was no fracture or other bone injury, but only profound laceration of the soft parts. The usual symptoms of death by fat embolism were present, and at the autopsy, emboli were found in pulmonary blood-vessels of large calibre as well as in the capillaries; also in a few glomeruli of the kidney. Pinner considered that the source of the fat here was the subcutaneous connective tissue, which was rich in it. He believes, too, that even in cases of fracture the soft tissues contribute to the fat producing the embolism, since experiments have shown that it is necessary that at least 210 grammes of fat must enter the circulation to cause death in an adult man, whose femur contains but 70 grammes. Hence some other source for fat must be found than the fractured bone, and none so likely as the soft parts simultaneously injured in fractures.

From the facts in his case, Vogt deduces that in cases of marked deformity after resection, close apposition of the cut surfaces of the bones should not be attempted, but free drainage should be secured. He further suggests that where there is marked fatty degeneration of bone, amputation and not resection should be performed. Dr. Park adds the use of every judicious means to increase the power of the heart to force the load of fat through the venous into the arterial system—digitalis, alcohol, strychnine, and, as he says, on purely theoretical grounds, inhalations of oxygen gas. He suggests that if the blood can thus be moved, the fatty matters will probably be emulsified or saponified by the alkalies in the blood. Such measures as these, together with promptness of treatment in all injuries of the kind referred to, seem to include at present all our resources in treatment.

DOES MALE COPULATION WITHOUT EMISSION INJURE FEMALE HEALTH?

IT has been commonly believed that if the act of sexual intercourse is incomplete, by not ending in the discharge of seminal fluid within the sexual organs of the female, uterine disease is liable to result. Some writers have even gone so far as to assert that malignant disease of the neck of the womb could thus be caused. The sin of Onan was again denounced; conjugal onanism was assailed with a new weapon, and the thunderbolts of physiological vengeance were launched against the unhappy women who permitted sexual intercourse without having the womb "refreshed and soothed" by half a teaspoonful or so of one of the cheapest of human secretions. Onanism is abominable, unnatural, and there is enough ground for its absolute condemnation without involving the help of an improbable hypothesis or downright error.

Ten years ago Bertillon, writing upon *Hygiène Matrimoniale*, declared that the assertion as to the beneficial influence of the spermatic fluid upon the uterus had no scientific ground, and justly criticised the hypothesis. Nevertheless, the assertion would not die; it was vitalized by the faith and proclamation of too many doctors, and has still kept rising to the surface of periodical medical literature at occasional intervals. But now, as we think, DR. VAN DE WARKER has given it the *coup de grâce*. This able investigator and accomplished gynecologist has published in the *American Journal of Obstetrics* for August, an important paper entitled "A Gynecological Study of the Oneida Community," and the influence of non-ejaculation upon the health of women is one of the topics considered. The rule of non-emission was observed in sexual intercourse in the Oneida Community, and in such continence, more unnatural than conjugal onanism, no discharge of semen takes place either before or after the withdrawal of the penis. Now it plainly follows that if the influence of the seminal fluid upon the cervix is so necessary for the healthy state of the womb, those women of the Community whose wombs had been for years repeatedly subjected to the venereal orgasm—in some cases intercourse took place oftener than seven times a week, a more than brutal licentiousness—and had not had a drop of seminal fluid in all this time to refresh and protect them from disease, those women ought to have shown a great prevalence of uterine disease.

Seven years ago Dr. Van de Warker was asked to examine the adult female members of the Community with reference to the possible injurious effects of the sexual practices observed. In answer to this request he began such examination, but after one-fourth of the members had been subjected to it, it was stopped by order of the head of the organization. Never-

theless, enough was learned by the examinations that were made to justify Dr. Van de Warker in stating that he could discover "nothing but negative evidence as to the effect of male continence upon the health of the Community."

THE PASSAGE OF SOLID PARTICLES FROM THE MATERNAL TO THE FŒTAL BLOOD.

While the passage of substances in the form of gas or in solution from the maternal to the fœtal blood has often been proved, it has generally been denied that solid substances may be similarly conveyed. Budin writing in 1877, in the *Dictionnaire Encyclopédique des Sciences Médicales*, refers to the single observation of Reitz, in which he found that cinnabar had passed from the blood of the mother to that of the fœtus, and regards the proof as not conclusive. He further adduces the negative evidence which Hoffman and Langerhans, Jassinsky, and Fehling have, after many experiments, given. He states that the passage of living formed elements, though easily explained by the theory of diapedesis, has never been ascertained; it is denied by Claude Bernard, and the experiments of Davaine, of Brauell, and of Bollinger prove equally that solid poisons, or those having form, are alike retained at the level of the two placentas, and cannot communicate their injurious action to the fœtus. While then the transmission of micrococci from the mother to the fœtus is regarded by Budin as disproved, he considers the fact of the latter being affected with variola, a disease which it is believed is dependent upon a microbe, as an inexplicable and contradictory fact.

Tarnier, in 1881, in his *Traité de l'Art des Accouchements*, is equally positive, stating that all experiments which have been made up to the present time prove that solid substances, even in a state of minute division, cannot pass through the membrane which separates the maternal from the fœtal blood. Charpentier, in 1883, also said that experiments tend to demonstrate that if liquid or gaseous substances pass, it is not true for solid substances, whatever the variety or however minute the division.

The recent investigations of Dr. J. P. Pyle contradict these generally accepted views, showing that solid particles and bacteria may be transmitted from the maternal to the fœtal blood. The experiments were made in the Pathological Laboratory of the University of Pennsylvania, under the direction of Dr. Formad, and hence have presumptive evidence of reliability. In nineteen pregnant rabbits, a solution of ultramarine blue was injected into the blood-vessels, and of the sixty-one fœtuses obtained from these animals, forty-six showed the presence of blue granules in their tissues. Further, septic matter was introduced into the tissues of ten pregnant rabbits, and not only the mothers were found to have bacteria in their blood, but these bacteria were also discovered in the blood of the fœtuses.

Dr. Pyle further had the opportunity of examining the blood of a pregnant woman after death from septicæmia, and also that of her dead fœtus, which was removed by Cæsarean section, and in the blood of each vast numbers of micrococci were found. If the correctness of these experiments is verified, an important advance in our knowledge of the relations between the maternal and the fœtal blood has been made.

In one part of his paper Dr. Pyle states that the walls of ordinary bloodvessels, through which white blood-corpuscles migrate in any part of the body, are not thicker than the membrane interposed in the placenta between the maternal and the fœtal blood, and hence he regards it as plausible that the blood corpuscles might pass through that membrane. We cannot regard his experiments as proving such transference of blood globules from the mother to the fœtus—a suggestion which is in the highest degree improbable. Leucocytes are three or four times more numerous in the fœtal than in the maternal blood, and if these entered the former to be used in the formation of red disks—this being one of the probable theories of the origin of the latter—those disks ought not to present such wide variations in size, so different in this respect from the maternal blood; further, the hæmoglobin in the fœtal is decidedly greater than in the maternal blood. The blood of the fœtus and that of the mother have these among other marked differences, and it is in the highest degree improbable that the former receives from the latter corpuscles white or red, but it still will be held that the fœtus makes its own blood as to the anatomical elements, while the plasma only is furnished by the mother.

THE LAW REGULATING THE SALE OF POISONS.

A law of Pennsylvania says that no one shall

"dispose of, by retail, any morphia, strychnia, arsenic, prussic acid, or corrosive sublimate, except upon the prescription of a physician, or on the personal application of some respectable inhabitant of full age of the town or place in which such sale shall be made, and in all cases of such sales, the word 'poison' shall be carefully and legibly marked or placed upon the label, package, bottle, or other vessel or thing in which such poison is contained."

A careful perusal of this clause shows that it is not as clear, or as comprehensive as it should be. It does not state whether it is intended to apply to sales *in bulk only* of the poisons mentioned, or also to mixtures and physicians' prescriptions containing them in such quantity that the dose directed is harmless, while a part or the whole quantity dispensed would be fatal to a person taking it.

To us it seems quite clear that all sales in bulk are

within the intent of the law, and that every bottle of the officinal solution of morphia or a solution of corrosive sublimate even of the strength of a grain or two to the ounce must be labelled "poison." But it is not clear that it was intended to apply to the combinations and prescriptions into which the substances named enter in such quantities, that the dose ordered is harmless. Such an interpretation would render the law almost disastrous in its consequences; and would make it necessary to label nearly every second bottle of medicine dispensed on a physician's prescription with the terrifying word "poison." Not only this, but every bottle of paregoric, and of Brown mixture, every box of Wistar's cough lozenges, and a hundred or more articles which are daily sold over the counters of druggists must be so labelled. The effect of this upon the mind of the average patient can easily be imagined. It has been within the experience of almost every physician to have a patient say the medicine prescribed was not administered, because the prudent apothecary had, by way of caution, suggested care in its use.

It seems scarcely necessary to dwell further on the utter absurdity of such an interpretation of the law. Yet a coroner's jury in this city recently declared that an apothecary's clerk was criminally negligent because he failed to place such a label upon a box of pills of which each contained one-twentieth of a grain of sulphate of strychnia. The pills were prescribed by a physician, and the dose ordered was one, "at meals." This verdict was rendered because it happened that of several persons who, in a spirit of banter, had taken a number of these pills, a young girl, who took fourteen, died.

Stupid as this action may seem, it may not be without its good result. The interpretation of the coroner's jury may be literally correct, but it is not the interpretation of intelligence, nor is it called for by the purpose for which the law was enacted.

That the law is not as comprehensive as it should be is shown by the fact that the few poisons named in the Act are but a small number of those the sale of which should be carefully regulated by law. The list should be enlarged to include aconite, atropia and its salts, cantharides, digitalis, and many others.

It is to be hoped that the unfortunate fate of the heedless girl and the inconvenience and annoyance to which the apothecary's clerk was subjected, may be the impulse which will secure an amendment to a law which is so obviously inadequate.

MODIFIED COLOTOMY.

IN the *Beilage zum Centralblatt für Chirurgie*, No. 23, 1884, may be found a suggestion of MADELUNG, of Rostock, in regard to the treatment of carcinoma of the rectum which is beyond the reach of extirpation. Instead of performing an ordinary lumbar colotomy, he cuts through the entire calibre of the gut, attaches its central end to the external wound, and returns the peripheral end, after closure of its lumen, into the cavity of the belly. The advantages of the procedure, in addition to diminishing the disposition to prolapse of the gut, are that it removes the mechanical, septic, and chemical irritation to which the carcinoma is subjected by the retention and passage of feces in the ordinary operation, and that it prevents the annoyance and discomfort which arise from the accumulation of feces between the lesion and the external sphincter.

WAS COLOR-BLINDNESS THE CAUSE OF THE LOSS OF THE TALLAPOOSA?

THE collision and sinking of the U. S. Steamship Tallapoosa, and consequent loss of life, it seems quite probable, may be another example of the results which we are called upon from time to time to chronicle of the baneful indisposition of our legislators to grapple with the subject of color-blindness in its relation to railroad service and navigation; any legal enactment concerning which is extremely unpopular with railway and steamship employés, who constitute an influential portion of our voting population.

A sailor, who says he was in the pilot-house of the Tallapoosa at the time of the collision, stated to an Associated Press reporter, that during the momentous minutes immediately preceding the collision "the captain, navigator, and mate saw the lights of the schooner, but disputed whether it was the green or the red light." And thus vital moments were wasted, and finally when the Captain decided what course to take, it was too late to avoid a collision.

In the official inquiry which is about to be held, we hope the Navy Department will direct a special investigation to be made by a medical expert concerning the color-vision and acuity of sight of all the officers and men whose duty it was to have seen the lights of the colliding schooner, and thus definitely determine if defective color-vision, the existence of which had not been previously ascertained, was responsible for the sinking of the Tallapoosa.

WE are glad to call attention to the excellent objection urged by our esteemed contemporary, the *New York Medical Journal*, to the general use of the word albumen. The white of egg, known in its entirety as albumen, is not identical with the precipitate from albuminous urine, and such being the case, the words used to indicate the two substances should not be identical.

SPECIAL ARTICLE.

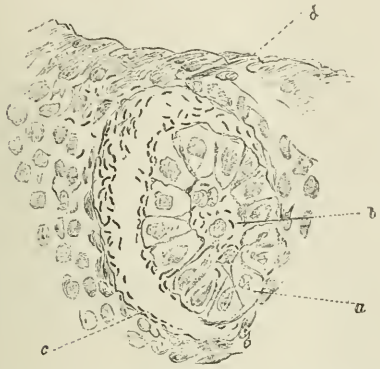
THE CHOLERA CONFERENCE AT BERLIN.

(Continued from page 223.)

THE Conference upon cholera at the Office of the Imperial Board of Health in Berlin, on the close of Dr. Koch's address, the conclusion of which we reproduce in abstract below, adjourned till July 29th, when it was occupied with several questions arising out of the discovery of Dr. Koch, upon which he made further observations. We hope later to give an outline of this meeting, which is reported verbatim in a supplementary issue of the *Berliner klinische Wochenschrift*, August 11th.

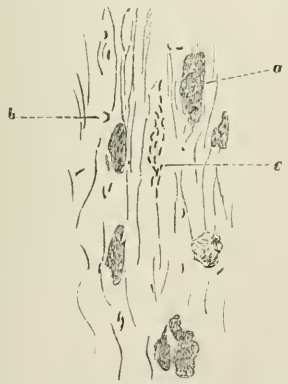
Before giving the conclusion of Dr. Koch's address we may draw attention to the subjoined illustrations of specimens which were exhibited, and referred to by him in that portion of his paper which appeared in our previous issue.

FIG. 1.



Surface of mucous membrane denuded of epithelium. Section of the mucous membrane of the cholera-intestine. (*a*) Tubular gland cut obliquely. Within it (*b*) and between the epithelium and the basement membrane are (*c*) numerous comma-bacilli. × 600 diameters.

FIG. 2.



Cover-glass preparation of contents of cholera-intestine. (*a*) Nuclei of dead epithelium. (*b*) Semicircular comma-bacillus. (*c*) Characteristic grouping of comma-bacilli. × 600 diameters.

CONCLUSION OF DR. KOCH'S ADDRESS.

Being thus convinced as to the distinctive characters of the common bacillus, the next thing was to determine the relation in which it stands to the cholera process, and whether it ever occurred in non-choleraic cases. In the ten examinations made in Egypt, this point was only tested microscopically, no cultivations having then been made. In India the intestines were examined in forty-two cases, both microscopically and by cultivations, and in not one was the bacillus absent; in very acute cases it was found almost unmixed. Choleraic dejecta from thirty-two cases yielded similar results, but in only two out of many observations on vomited matter were bacilli found. It was probable that in these two cases the vomit contained fecal matter. Bacilli were also found in specimens from eight cases sent by Drs. Kartulis and Schiess-Bey from Alexandria, and in two cases examined at Toulon in conjunction with Drs. Strauss and Roux, and in the choleraic dejecta of two other cases. One of these Toulon cases was that of a sailor attacked with cholera when convalescing from malarial fever; he died four hours after the seizure, and the autopsy was made half an hour after death, it being always an object to make such an examination as soon as possible. In this, as in other acute cases, the intestines contained almost a pure growth of the comma-bacillus. The other Toulon case was similar, but in neither was the microbe found by Strauss in Egypt detected in the blood.

Thus the comma-bacillus has now been found in nearly one hundred cases of cholera, occurring in a constant relation to the cholera process, being most abundant in the lower end of the ileum, where the changes are most intense, and being most pure in the acute uncomplicated cases. On these grounds the comma-bacillus may be considered as specific to cholera. Many observations were made in other diseases, and in subjects who had recently passed through attacks of cholera, without finding these bacilli in the dejecta or in the bowels. These observations included cases of dysentery, typhoid fever, bilious typhoid, and infantile diarrhœa; the secretions of the mouth, which are so rich in bacterial life; the intestines in arsenical poisoning; but, although bacteria of all kinds were met with, the comma-bacillus was conspicuous by its absence. Similar negative results followed examination of the drain-water of Calcutta, and the impure tank-water in the villages on the banks of the Hooghly. Once only in the water flooding the region of the salt water lake east of Calcutta was a bacterium found at first sight resembling the cholera bacillus, but on further scrutiny it proved to be thicker, and not to have the power of liquefying gelatine. In his own experience and that of other bacteriologists, a similar form to the comma-bacillus was unknown. Three different views as to its relation to the cholera process are tenable:

1. That the disease favors the growth of these bacilli by affording them a suitable soil. If so, it would mean that the bacillus in question is most widely diffused, since it has been found in such different regions as Egypt, India, and France; whereas the contrary is the case, for the bacilli do not occur in other diseases, nor in the healthy, nor apart from human beings in localities most favorable to bacterial life. They only appear with the cholera,

2. It might be said that cholera produces conditions leading to a change in form and properties of the numerous intestinal bacteria—a pure hypothesis; the only instance of such a conversion refers to a change of physiological and pathogenic action, and not of form. Anthrax bacilli under certain conditions lose their pathogenic power, but undergo no change in shape; and that is an instance of a loss of pathogenic properties, whilst there is no analogy to support the view of the harmless intestinal bacteria becoming the deadly cholera bacilli. The more bacterial morphology is studied, the more certain is it that bacteria are constant in their form; moreover, the comma-bacillus retains its special characters unchanged through many generations of culture.

3. Lastly, there is the view that the cholera process and the comma-bacilli are intimately related, and there is no other conceivable relation but that the bacilli precede the disease and excite it. "For my own part," said Dr. Koch, "the matter is proved that the comma-bacilli are the cause of cholera."

If this be so, experimental confirmation of the fact might be expected; and, were authors to be trusted, there should be no difficulty in this, since it has been stated that cholera occurs in cattle, dogs, fowls, elephants, cats, and other animals. But there is no evidence of such animals being spontaneously attacked with the disease during cholera prevalence: and direct experiments have either proved negative, or, if positive, have been inconclusive or been contradicted by others. The experiments of Thiersch on white mice, to which so much importance has been attached, have been repeated by Koch with recent and with decomposing choleraic material, the mice remaining unaffected. Experiments were also made upon monkeys, cats, fowls, dogs, and various other animals, but nothing like a cholera process was observed; and a similar result followed experiments with the comma-bacillus in all stages of its development. Animals were fed with large quantities of the comma-bacillus, with the result that the bacilli were found to be destroyed in the stomach, none appearing in the intestinal canal. It is not so with other bacteria—*e. g.*, a red micrococcus found in Calcutta. Dr. Barclay fed mice with this micrococcus and obtained cultures of it from the intestinal contents. The bacillus was injected directly into the small intestine and into the large bowel of monkeys, but without result; nor was any better success obtained by such measures employed after irritants had been introduced into the intestine. The only experiment which at first seemed to promise results was when pure cultures were injected

into the blood of the rabbit or into the abdominal cavity of the mouse. The rabbits became very ill after the injection, but recovered; the mice died in from twenty-four to forty-eight hours, and the comma-bacillus was found in the blood. It would seem as if, unlike other experiments on infective disease, very large quantities of the virus had to be employed; but to assure himself of the capability of infecting animals with cholera, Koch made special inquiry as to whether animals in India ever had the disease. He learnt that in the densely populated province of Bengal, where many kinds of domestic animals are to be found under conditions favorable for infection, cholera was unknown among them. They appear to enjoy an immunity, and are incapable of being experimentally infected—a fact which is not fatal to the view that the comma-bacillus is pathogenic; for, apart from experimentation, no other explanation of its connection with cholera is possible than the causal one.

Leprosy is not communicable to animals, and yet the lepra bacillus must now be regarded as the cause of the disease. It is probably the same with typhoid fever, which is not communicable to animals. It is enough to ascertain the constant occurrence of a special kind of bacterium in a disease, and its absence in other diseases, its occurrence corresponding with the pathological lesions and the course of the disease. And there are some animal diseases not transmissible to man —*e. g.*, rinderpest and pleuro-pneumonia. Parasites have their special hosts; many kinds of animals have their own tapeworm, which cannot develop in any other. Again, there is a whole group of diseases, especially the exanthemata, conceivably dependent on micro-parasites; but no one has ever yet shown that a disease can produce a specific organism. In cholera we have instances amounting to actual experimental infection of man—*e. g.*, the infection of those who are engaged in washing linen soiled by choleraic dejecta. Such linen contains the bacilli often in a pure form, and if infection occur through this medium, it must be by means of the comma-bacilli, the only microörganism present. The hands may be soiled and the bacilli introduced into the mouth by direct contact or through the food, or drops of the washing water may come in contact with the lips, and thus in some way the human being is fed with a small quantity of a pure culture of comma-bacilli. Another instance was found by Koch in the case of a tank of which the water was used for drinking and other purposes by many people among whom cholera was raging. He found the comma-bacilli in this tank, and learned that the linen of the patients was washed in it. Around the tank were some thirty or forty huts, inhabited by two hundred or three hundred people; of these, seventeen died, the number taken ill not being ascertained. The tank also received the refuse from the dwellings. The Hindoos bathe in the tank, wash their utensils in it, and deposit excreta on its shore; and if a hut has a latrine, its outflow is into the tank. Now, it was found that after a time the bacilli became less abundant in this water, and coincidentally the cholera declined; whereas, had the epidemic been the cause of their presence, and not the result, the number of bacilli should have increased in it.

The whole etiology of cholera, so far as it is known, suggests the view taken as regards the comma-bacilli. They multiply rapidly, soon reach their term, and are supplanted by other bacteria. So in the intestine they multiply, set up irritation and diarrhœa, and all the typical symptoms of the choleraic seizure. Under normal conditions—in animals at least—the bacilli are destroyed in the stomach, and this harmonizes with the important part played by predisposition, and the liability of those to be attacked who are suffering from gastric or intestinal catarrh, or who have overladen the stomach with undigested food, conditions which would facilitate the passage of the bacilli unchanged into the intestine. But the bacillus is limited to the intestine; it is not found in the mesenteric glands or in the blood. How, then, can it destroy life? Probably from the production of a poisonous substance, such as is produced by bacteria in putrefaction. In a gelatine culture of the comma-bacilli with which blood-corpuscles were mingled, the corpuscles became destroyed as the colony grew, and it is probable that the bacilli exert a like destructive influence on other cells. That some poison is produced gets confirmation from the experiments of Dr. Richards, of Goalundo, who fed pigs with choleraic material, death ensuing from convulsions in from fifteen minutes to two and a half hours. This must have been due to "intoxication," and not, as Dr. Richards states, to choleraic infection, for another pig, fed on the intestinal contents of one of those so killed, remained healthy. If it had been choleraic virus, it should have been transmissible. These experiments prove that in cholera the dejecta contain certain substances poisonous to swine, whereas dogs, mice, and other animals are unaffected by it.

Assuming that the bacilli produce a specific poison, the phenomena of cholera may be thus explained: The poison acts locally in destroying the mucous membrane, and, being absorbed, it acts generally, and especially paralyzes the circulatory organs. All the symptomatology of cholera, usually considered as due to the loss of water and thickening of the blood, is explicable on this view. Death may occur in this stage of cholera-poisoning when but few local changes are found, and the intestinal contents exhibit a pure culture of bacilli. If this stage be passed through, there occur necrotic changes—hemorrhages and putrefaction—with symptoms due to the absorption of putrefactive products, usually described as cholera-typhoid. And there is abundant evidence of the cholera virus occurring in the dejecta, and rarely in the vomit. For the further dissemination of the disease it is necessary that the dejecta should be retained in the moist state, for drying destroys their potency; and this fact is borne out by the spread of the disease through the water supply, or more directly by soiled hands, or even conveyance through insects, or blow-flies to food. Drains may be infected, and through them the water supply. As the virus cannot be retained in the dry state, aerial infection seems impossible; nor has cholera ever been conveyed by merchandise or by letters, even if these are not disinfected and fumigated. Cholera can only be spread by human intercourse—a fact sometimes wanting in proof because it is overlooked, for the mildest case may be as infective as the most severe. The diagnosis of such mild cases by the detection of the comma-bacillus becomes thus of much importance.

That the virus can be reproduced and multiplied out-

side the body is apparent, since the bacillus can be cultivated artificially, and its growth is not affected by comparatively low temperatures. Probably it does not grow in streams and rivers, where, owing to the current, a sufficient concentration of nutrient substance does not occur; but in stagnant water and at the mouths of drains, etc., vegetable and animal refuse may accumulate and afford the necessary nutriment. Thus is explained the propagation of cholera by the subsoil water, and the increase of epidemics with the sinking of its level, which lessens the flow and diminishes the amount of surface water.

Admitting the dependence of cholera upon this microorganism, it is impossible to conceive the disease having an autochthonous origin in any particular place; for a bacillus must obey the laws of vegetable life, and have an antecedent; and since the comma-bacillus does not belong to the widely diffused microorganisms, it must have a limited habitat. Therefore the occurrence of cholera on the delta of the Nile does not depend on its resemblance to the delta of the Ganges; but the disease must have been imported there as it is into Europe. It was once thought that an outbreak in Poland had a local origin until it was discovered to have been introduced from Russia. Again, about ten years ago, there was a sudden outbreak at Hamar (Syria), thought to be an instance of local origin, but erroneously, as shown by a statement of Lortet, who told Koch, when at Lyons, that the epidemic had been introduced into Hamar, where he was at the time, by Turkish soldiers from Djeddah. Indubitable instances of local epidemics arising outside India are not known, and everything confirms the view gained by experience that the cholera is due to a specific organism having its home in India. It used to be thought that the disease had started from Ceylon, Madras, or Bombay, but there is now general concurrence in regarding Bengal, the delta of the Ganges, as the original source. This is the only region where the disease never varies from year to year, for although some other regions, as Bombay, are never free from it, yet it is highly probable that this is due to its continued reintroduction. The upper region of the Ganges delta is thickly populated; the lower district, Sondarban, covering an area of 7500 English square miles, is uninhabited, and here the Ganges and Brahmapootra break up into a network of watercourses. The district abounds in luxuriant vegetation and in animal life, and is the seat of inundations and the home of pernicious fevers. Here it is probable, where the vast amount of decomposing vegetable and animal life affords a suitable soil, that the cholera bacillus flourishes. All great epidemics begin with an increase of cholera in South Bengal. The inhabitants of Lower Bengal dwell in huts raised on mounds to protect them against inundation, the excavations thus formed making the so-called "tanks," which are very numerous in the district of Calcutta and its vicinity. Since 1870, when new drainage works and water supply were introduced, the mortality from cholera in Calcutta has become much reduced; but the retention of many of these tanks and the nature of the native dwellings still account for the spread of the disease. A remarkable instance of the disappearance of cholera under improved water supply is afforded by Fort William, which used to have many cases annually. Other Indian towns show the same good result of improved water supply—*e. g.*, Madras, Bombay, and Pondicherry, where some years ago the formation of artesian wells banished cholera; and although cases reappeared there last spring, Dr. Furnell, of Madras, ascertained that the cases were limited to the part of the town not yet supplied with these wells.

Although contamination of drinking water may be the chief mode of spread, this is not the only way, and each place has its own conditions, which have to be dealt with. The diffusion of cholera in India depends on human intercourse, especially on pilgrimages, which are carried on to an inconceivable extent—*e. g.*, hundreds of thousands flock yearly to Hurdwar and Puri, remain there many weeks herded together, bathing in the tanks that supply them also with drinking water. Over the borders of India the cholera is carried into Persia, and, in the old caravan days, thence to the south of Europe; but the route is now by the Red Sea and Suez Canal. Every year the danger to Europe by this route increases, for Bombay, which is seldom free from cholera, is but eleven days distant from Egypt, sixteen from Italy, and eighteen or twenty from France. It is also clear that the greatest danger lies in ships carrying large numbers of people, as troops, pilgrims, coolies, and emigrants, and not to the merchant vessels with small crews, for in the former the outbreak of an epidemic would be likely to last till Europe was reached. In the reports of the Sanitary Commissioner of India, 1881, it is stated that out of two hundred and twenty-two coolie ships, carrying from three hundred to six hundred, which had left India for American colonies in ten years, thirty-three had cholera on board, and in sixteen the epidemic lasted more than sixteen days.

Why outbreaks of cholera outside of India die out is probably due to different factors. One is that an attack of cholera confers immunity, at least during the period of one epidemic, and whole districts may enjoy a similar immunity for a time; cholera having been in the place one year, passes it by in the next. Another is, that the bacilli do not pass into the "resting state." And a third is the check given to their development by temperatures below 17° C.

In conclusion, Dr. Koch adverted to the subject of treatment, and reminded those who say that such discoveries do not enable us to cure the disease better than formerly, that a rational treatment of most diseases, and especially of infectious diseases, cannot be adopted until their cause and nature are known. But even yet the discovery of the cholera bacillus is important, as furnishing an aid in diagnosis which would facilitate the detection of the first case occurring in a district, and the adoption of measures to prevent its spread. Knowing also the nature and properties of the bacillus, and especially the readiness with which it is killed by drying, the right direction of prophylaxis is assured, and the lavish expenditure of disinfectants checked, so that there will not be a repetition of what happened in the last epidemic, when millions of gallons were poured into the gutters and sewers without the slightest need. Even therapeutically, the knowledge of the comma-bacillus may be of value. Diagnosis will be possible in mild cases, and in the early stages of the disease, when treatment is of most avail.

STRAUSS AND ROUX'S CHOLERA RESEARCHES AT TOULON.

In connection with Dr. Koch's remarks it will be interesting to read the following statement which MM. Strauss and Roux have recently submitted to the Académie de Médecine as the result of their researches on the cholera at Toulon. These researches are the continuation of those begun in Egypt, with Thuillier and Nocard, in 1883. Eighteen autopsies were made under very favorable conditions, and the dejecta, vomit, and urine of numerous patients were placed at their disposal. The first autopsy made dispelled all doubt as to the nature of the disease.

As is well known, repeated efforts were made in Egypt to discover a specific organism in the intestinal coats which could be held responsible for the disease and the lesions. At Toulon these efforts were renewed.

According to Koch, the cholera in Egypt and that in India was characterized by the presence in the intestinal mucosa of a characteristic bacillus. The observations made by MM. Strauss and Roux at Toulon fully confirm those they made in Egypt, to wit: that in the intestinal mucous membrane of certain cholera patients the most diverse organisms were found, especially if the disease had lasted for some time. But in the more rapid cases they were much less numerous, and in subacute cases could not be found at all. Of the eighteen intestines of cholera cases examined at Toulon, eleven, or more than one-half, contained no microörganisms, in spite of the most careful examination. Upon conference with Dr. Koch, on his arrival at Toulon, they found that their methods of coloring were identical with his. They maintain, therefore, that in a large number of cases of cholera (and particularly in the more characteristic cases) no microörganisms are found in the intestinal tunics.

In his fifth and sixth reports, from Calcutta, Koch gives precise details as to the organism which he regards as the cause of cholera. The cholera bacillus, he says, is not entirely straight, but more or less curved, etc. At Toulon, while wishing to show his methods for finding the microbe, he used no special color-procedure. A small amount of dejecta was spread out in a thin layer and dried; the preparation thus obtained was slightly heated and colored with an aqueous solution of aniline or methylene blue. When, as was systematically done at Toulon, MM. Strauss and Roux examined the characteristic cholera stools, it was seen that they contained a great number of different microorganisms, and in many cases there were a small number of comma-shaped organisms. The intestinal contents, removed from the bodies under the most favorable circumstances, showed also, in the greater number of cases, various kinds of microörganisms, among which were the comma-bacilli, but they did not seem to predominate over the others. In thirteen cases, also, examinations, made under favorable circumstances, of the contents of the small intestine, showed the comma-bacilli in large numbers in three cases; in four cases only a small number were found; and in five cases they were absent. It is true that the conditions regarded by Koch as particularly favorable for finding the comma-bacilli are of short duration; according to him only the stools which are fecal from the commencement of the attack, and not those which are passed during the period of reaction are favorable; and he recommends the examination of the contents of the small intestine—taken promptly from a subject who has died during the algid period of a rapid case of cholera.

In a fulminant case, the autopsy of which was made by Koch, MM. Strauss and Roux found the small intestine lined with a sort of grayish-white, stringy mucus, a portion of which, when spread out in a thin layer and colored, showed a large quantity of comma-bacilli. They were, so to speak, in a pure culture in this mucus. In the eighteen autopsies which they made, they found in one other case, in which death had supervened very quickly, the same appearance in the small intestine, and the same abundance of the comma-bacilli.

These cases are very seductive, and lead one to accord an important *rôle* to the comma-bacillus in cholera; but there are others, and they are the more numerous. The variety of organisms which is found in the intestinal contents is so great that no one appears to preponderate over the others. In these cases Koch resorts to culture in order to bring out the comma-bacillus.

During cultivation, these organisms are sometimes joined end to end, and then take the form of an S, or the form of spirilli. It is this appearance of the culture in gelatinized bouillon which Koch regards as characteristic. The comma organism requires an alkaline medium for its development, and multiplies with great rapidity in most alkaline media at a temperature between 60° and 107° Fah. It is certain, then, that there often exists in the rice-water discharges, and in the intestinal contents of cholera patients, a bacillus shaped like a comma; and that in certain cases this bacillus is found in a state of almost purity in the mucus lining the intestine. Is one justified in concluding that the comma-microbe is the organism of cholera? MM. Strauss and Roux answer no. In default of the direct proof which the inoculation of the comma-microbe upon animals would furnish (and all such experiments have so far failed), Koch is obliged to show that the organism which he describes is only found in the intestine of the cholera patient, and never in the healthy man, or in persons with any other disease than cholera. And to do this a great many experiments would have to be made, for it would be only necessary to find it once in a disease other than Asiatic cholera to settle the question definitely. Furthermore, the comma organism cannot of itself be regarded as characteristic of cholera, for it has been found in products which have nothing to do with cholera. Maddox, of London, has photographed a comma-shaped microbe, which he found in a reservoir of water; and Malassez has shown them, in a preparation of dysentery stools, and amongst many other organisms, bacilli of a well-characterized comma form. In the vaginal mucus of women with leucorrhœa, and in the mucous uterine secretion of a woman who had commencing epithelioma of the cervix, they have found bacilli of a comma shape like those of cholera. The comma form is not, therefore, characteristic of cholera. It is very important to try, in the cases which they have cited, to isolate by cultivation the microbes which have a similar form with those described by Koch, and to see how they comport themselves in different media. This is the only way in which they can be distinguished.

If the comma-bacillus be the true cause of cholera, as

it only resides in the contents of the intestines, and as in the rapid cases it does not invade to an appreciable extent the intestinal mucosa, it must be admitted that, in order to produce such rapid and intense effects, it secretes a soluble ferment, a ptomaine, or some poison, very energetic, which causes symptoms of cholera when absorbed. Attempts should therefore be made to extract from the pure cultures in which the bacilli have lived, a soluble poison which will reproduce in animals symptoms analogous to those observed in cholera patients. It would be also interesting to know if the comma-microbe is found in cholera nostras.

In their report on the cholera in Egypt, MM. Strauss and Roux mentioned the presence in the blood of cholera patients of extremely fine particles resembling organisms. At Toulon the same appearance was observed in many cases, but was wanting in a few. They think that these particles are due to a special alteration of the hæmoglobin, and this opinion is in accord with that of Malassez.

REVIEWS.

The Laws of Health: Physiology, Hygiene, Stimulants, and Narcotics. For Educational Institutions and General Readers. Copiously illustrated. By Joseph C. Hutchison, M.D., LL.D., Author of a Treatise on Physiology and Hygiene; Ex-President of the New York Pathological Society, etc.; late President of the Medical Society of the State of New York, etc. Pp. 223. New York: Clark & Maynard.

The production of this volume of popular hygiene and care of the health, by a gentleman of Dr. Hutchison's eminence in the profession, is a step, and a long step upon good firm ground, in the right direction. The more it is possible to educate the rising generation, the hope of America, in the judicious management of their own bodies so as to prevent disease and premature death, the more certainly may we expect an improved race of mankind to follow in our footsteps. And just in proportion as we can aid to dissipate the shadow of ignorance which covers the bodily functions in health and illness among the people, will we deliver them from the dominion of the various medical heresies and delusions, which prey upon their longevity, vigor, and estates, and contribute our professional share toward discharging the great philanthropic duty of leaving the world better than we found it.

This work is singularly adapted to the object it has in view, being throughout strictly accurate and thoroughly scientific in statement, and yet at the same time perfectly clear and comprehensible to even a child's intellect. The dryness of mere anatomical detail is made interesting by the association with it of descriptions of function, and practically useful by demonstrating the invaluable assistance afforded by this kind of knowledge to human beings in their great business of preserving health.

The bones, muscles, and skin are first considered; then follow chapters upon food and drink, digestion, circulation, and respiration; the nervous system, the special senses, and the voice being appropriately discussed after the attentive pupil has gained a general comprehension of nature's methods of construction and operation. A valuable appendix contains directions for the treatment of poisoning, drowning, and other medical or surgical emergencies, comprising a most important part of that general medical knowledge which it is the duty, and should be esteemed the privilege of every true physician to popularize on all suitable occasions.

The numerous figures of this book are excellent, and admirably illustrate what they are intended to aid in explaining, and, indeed, the mechanical execution in every respect reflects great credit upon the publishers.

Dr. Hutchison's Laws of Health comprise one ordinance in regard to alcohol, which he declares on p. 52, the organs of the body "abhor," that will, no doubt, stir up much adverse criticism of the volume, which, however, we think it will prove itself quite able to endure without serious injury. On the other hand, it should receive everywhere enthusiastic praise from the advocates of temperance, whose views it teaches so earnestly, and yet with the exception quoted above, so justly and temperately, as to commend the exposition to honest seekers after truth, upon this momentous question of the day, and still more of the coming century.

CORRESPONDENCE.

RAPID GENERALIZATION.

To the Editor of The Medical News.

Sir: As we claim for medicine the name of a science, or, rather, a group of sciences—etiological, pathological, diagnostic, and therapeutic—it is important for the cautious scientific spirit to be cherished in our investigations. Is it always so of late?

I do not propose to add now to the discussion of the *bacillus tuberculosis;* merely observing that the published results of Wargunin (mentioned in an editorial in The Medical News of August 9) strongly confirm the view that all needful evidence is not yet in on that subject.

Dr. Robert Koch is a splendid minute observer and patient master of mycological experimentation; but it does not follow that he is also a master of inductive and deductive reasoning. Cholera is not a new subject of investigation, although the comma-shaped bacillus is so stated to be. As to this, however, *Science*, of July 25, 1884, contains the following statement: "In the report of the Surgeon-General of the Navy for 1881 (Washington, 1883, p. 70) are to be found photo-micrographs, and a short account of a comma-shaped bacterium, a rather unusual form, observed by Surgeon J. H. Kidder in water through which air had been aspirated (summer of 1881), and in well-water near Washington (1883). . . . . Dr. Kidder supposed the form which he photographed to be the same as, or very similar to, that noted and figured by Billroth (*Untersuch. über Coccobacteria Septica*, Berlin, 1874, taf. ii., B. C.), found in the droppings from an imperfect water-faucet in his work-room, and called by him syphonomyxa nostocomii Vienniensis."

While, however, the asserted association of the comma-bacillus with cholera belongs clearly to Dr. Koch, it is not too great boldness to follow such an authority as Virchow in denying, as he is reported to

do, that the bacillus has not yet been proved to be the *cause* of cholera. Several things are in the way of this. Why should no bacilli be found in the stomach, as well as in the intestines? Surely, the rice-water vomit is as characteristic as the discharges from the bowels. Especially is this notable in connection with the current supposition — very erroneously called a "demonstrated fact"—that drinking-water, specifically contaminated, is the only medium of propagation of the disease. How can bacilli enter by drinking-water, except through the stomach?

Pasteur has well criticised some of Koch's practical recommendations. The latter, for example, fears the proposed purifying use of water, because drying most rapidly kills the bacilli. Yet abundant evidence everywhere establishes the beneficial action of water, freely used, as Nature's best disinfectant; most efficient, it is true, in the form of highly heated steam.

Consul Mason's acceptance of the "transportation" of the cholera all the way from China, in a specified vessel, at a time when no cholera was known to exist in that country, and when the official head of the French Naval Sanitary Bureau denied the fact of any such conveyance, was quite too ready, originating, no doubt, in the same conviction (viz., that there must have been some such transportation) as that which induced Dr. Koch to assert that it was brought by some English vessel whose officers falsified its health record.

Such strong effect do prepossessions in favor of foregone conclusions have upon the minds of men in and out of the profession, that facts glaringly in the way of these conclusions are systematically ignored. Of this nature, in regard to cholera, are some facts amply authenticated and publicly recorded from time to time. I may mention now only the following: During the summer of 1854, two packet-ships of the Copes' Line, between Liverpool and Philadelphia, the "Tonawanda" and "Tuscarora," were attacked with cholera in mid-ocean (the former two weeks out from port) when no cholera at all existed at Liverpool when they left. Conversing recently on these occurrences with a member of the shipping firm which was then running those packets, he stated to me his knowledge also of one instance in which a ship going from *Philadelphia toward Liverpool*, when no cholera existed at either place, was attacked in midocean with the disease.

If we had some of the patience in getting *all* the facts which led Kepler to try nineteen other hypotheses before concluding on his three great laws, and which induced Newton to delay for years the announcement of his law of gravitation, because a few facts concerning the moon's motion did not appear to agree with it, medical science would gain in credit and usefulness. If, for example, the idea which commonly prevails in India were regarded at least with some question and toleration in Europe and America, that cholera is not contagious, but a *migratory epidemic*, travelling on its own caprice, and fastening upon filth-spots wherever it goes, the annoyances, not to say horrors, of lazarettos would be abolished, and rational measures of sanitary improvement would go on to extinguish the disease. It is satisfactory to know that a British commission is about to proceed to study cholera in India. One, at least, however, of those named upon it is, from his antecedents, sure to see microbes chiefly; and one must see some things besides microbes to reach valid scientific conclusions on so large and many-sided a subject.

Henry Hartshorne, M.D.

Philadelphia, August 26, 1884.

OBITUARY.

Surgeon Joseph Janvier Woodward, U. S. A.

Brevet Lieutenant-Colonel Joseph Janvier Woodward, Surgeon, U. S. Army, who died near Philadelphia, on Sunday, August 17, 1884, at 1 P.M., was born in Philadelphia, October 30, 1833, and at the time of his death was not quite fifty-one years of age. He was educated at the Central High School of that city, and, in 1850, received the degree of A.B. He devoted himself to the study of medicine, and graduated from the University of Pennsylvania in 1853. Two years later, in 1855, he received the degree of A. M. from the Central High School, acting as the valedictorian of his class. Immediately after his graduation, he entered energetically upon the practice of his profession in his native city, devoting a large portion of his time to that branch in which he afterwards achieved such a decided success—the microscopical investigation of pathological anatomy, and of kindred subjects. On May 17, 1858, he read before the Biological Department of the Academy of Natural Sciences, in Philadelphia, a paper "On the Minute Anatomy of Three Cases of Cysto-carcinoma," which will be found on page 54 of The American Journal of the Medical Sciences, for July, 1858. Other papers, read before the same Society, followed rapidly: "Remarks on Anatomical Diagnosis of Cancer," November 15, 1858; "On Suppuration in Cancerous Growths," March 21, 1859; "On Errors in the Anatomical Diagnosis of Cancer," December 4, 1859; and "On a Secondary Cancer of the Axilla," January 16, 1860.

When the war broke out in 1861, he offered his services to his country, and entered the Army as Assistant Surgeon, U. S. A., on August 5, 1861. He was with the Second Artillery, in the Army of the Potomac, until May 19, 1862, when he was assigned to duty in the office of the Surgeon-General in Washington, where he located and organized several hospitals, and, for a brief period, was in charge of the Patent Office Hospital. Relieved from this duty, he was placed in charge of the Pension Division of the Surgeon-General's Office and of the Medical Section of the Army Medical Museum, which had then been opened for the collection of specimens of morbid anatomy, surgical or medical. At the same time, the task was assigned to him of collecting the material for the *medical* portion of the *Medical and Surgical History of the War*, while his colleague, Dr. Otis, had charge of the collection of material for the *surgical* history and the surgical branches of the Museum collection. Both these officers prepared reports on the material available, which were published as "Circular No. 6" of the Surgeon-General's Office, on November 1, 1865. The second half of the circular, which was very favorably received by military surgeons, was prepared by Dr. Woodward. In the following year, he made a report "On Epidemic Cholera in the Army of the United States during the Year 1866," which appeared as "Circular No. 5," Surgeon-General's Office,

on May 4, 1867, and which was followed in June, 1868, by "Circular No. 1:" "Report on Epidemic Cholera and Yellow Fever in the Army of the United States during the Year 1867."

In the meantime, the collection of the material for the *Medical History of the War* had progressed rapidly, and, on November 12, 1870, he issued his first volume of 726 pages, quarto, containing a series of statistical tables, presenting a summary view of the facts embodied in the monthly reports made to the Surgeon-General with regard to the sickness of the Army, the deaths and the discharges on surgeon's certificate of disability.

After the close of the war, he had returned with increased fervor to his investigations in microscopy, and especially in photo-micrography, and the results of his experiments, which made him famous in Europe as well as at home, were given in a series of publications which followed each other in rapid succession:

Report on the Magnesium and Electric Lights as applied to Photo-micrography. 6 pp., 4to., 11 photographs. Surgeon-General's Office, 1870. *Report on the Oxy-calcium Light as applied to Photo-micrography.* 3 pp., 4to., 2 photographs. Surgeon-General's Office, 1870. *Report on an Improved Method of Photographing Histological Preparations by Sunlight.* 10 pp., 4to., 11 photographs. Surgeon-General's Office, 1870. *Report on the Histology of Minute Bloodvessels.* 8 pp., 4to., 11 photographs. Surgeon-General's Office, 1871. *Report on the Minute Anatomy of Two Cases of Cancer.* 10 pp., 4to., 2 photo-lithographs. Surgeon-General's Office, 1872. *Memorandum on Pleurosigma Angulatum and Pleurosigma Formosum.* 4 pp., 4to., 8 photographs. Surgeon-General's Office, 1871. *Memorandum on Surirella Gemma.* 1 p., 4to., 2 photographs. Surgeon-General's Office, 1871. *Memorandum on the Test Podura.* 3 pp., 4to., 5 photographs. Surgeon-General's Office, 1871. *Memorandum on Amphipleura Pellucida.* 1 p., 4to., 2 photographs. Surgeon-General's Office, 1871. *Memorandum on the Nineteen-band Test-plate of Nobert.* 4 pp., 4to., 9 photographs. Surgeon-General's Office, 1872. *Four Letters to the Surgeon-General, accompanying Photographs of the Mosquito, certain Parasites, the Proboscides of certain Flies, and Miscellaneous Photographs of Insects and Parts of Insects.* 8 pp., 4to., 35 photographs. Surgeon-General's Office, 1872. *Remarks on Photographic Micrometry in Trans. of the American Medical Association, 1876; Application of Photography to Micrometry, with Special Reference to the Micrometry of Blood in Criminal Cases. Ibid.*

In 1876 he had charge of the representation of the Medical Department of the United States Army at the International Exhibition at Philadelphia, and the success of the medical exhibition was mainly due to his energy and activity. During the succeeding two years he devoted himself entirely to the preparation of the second *medical* volume, which appeared on March 25, 1879. The work treats on the "Alvine Fluxes," and will be a lasting testimony of the zeal and indomitable perseverence of the author. In careful and painstaking research of the literature of the subject, it surpasses all previous publications. The anxious pursuit of this work had gradually undermined his constitution, never very robust, and, in the summer of 1880, he went to Europe to regain his health. He returned in a somewhat improved condition, but unfortunately was again prostrated by a fall from his horse in the spring of 1881, by which he fractured his leg. Barely recovered from this accident, he was called, in July, 1881, to the bedside of the lamented President Garfield. His quiet and patient services, frequently under a flood of abuse from professional as well as non-professional journals, in this new field of action are too recent to need to be recalled. We will only here state that he kept full notes of daily, even hourly observations of the patient's condition, which he intended to publish as a defence, if such were needed, at some future time. Sickness and death have despoiled him of this opportunity.

Time and space have allowed us to refer only to a few of the numerous publications of this indefatigable worker. A close observer, tenacious in his convictions of what he conceived to be right, writing to the point without flourish or embellishment, fearless in the expression of his views, courting rather than avoiding criticism, he was ever ready to enter the lists in defence of his opinion.

Dr. Woodward's last editorial work was his obituary notice of his colleague Otis, which appeared in the AMERICAN JOURNAL OF THE MEDICAL SCIENCES, July, 1881.

"For faithful and meritorious services during the War," Dr. Woodward received the brevet ranks of Captain, Major, and Lieutenant-Colonel, and on June 26, 1876, was promoted to the rank of Major and Surgeon. He became a member of the American Medical Association in 1865, and in 1881 was chosen its President, being the first medical officer from the Army to whom this honor was accorded. He was a member of the College of Physicians of Philadelphia, of the National Academy of Sciences, of the Philosophical Society of Washington, an honorary member of the Royal Microscopical Society and of the Quekett Club of London, of the Liverpool and Belgian Societies of Microscopy, and of many other societies in this country as well as in Europe.

His decease adds another name to the list of prominent men connected with the Surgeon-General's Office, whom death has removed within the brief period of three and a half years. On February 23, 1881, occurred the death of G. A. Otis, the famous author of the history of the surgery of the war. Two years later, on April 5, 1883, Brigadier General J. K. Barnes, who had watched by the bedsides of two martyred Presidents, passed away, and, on October 10, of the same year, Surgeon-General C. H. Crane, at whose suggestion both Woodward and Otis had been selected as the compilers of the Medical and Surgical History, died after a brief illness.

NEWS ITEMS.

YELLOW FEVER ITEMS.—The case of yellow fever taken off the U. S. S. "Galena," at Key West, Fla., has recovered, and no further cases of the disease have appeared, either on the "Galena" or at Key West.

Sanitary Inspector Ross, stationed at Nogales, Arizona, reports that he examined 149 passengers on the Sonora Railroad, from the infected districts of Mexico, fumigated their baggage, and quarantined 29 through passengers to the United States. He reports 9 deaths from

yellow fever at Hermosillo on the 10th inst., 6 on the 11th, and 4 on the 12th, among them a Catholic bishop.

The U. S. Consul at San Juan, Porto Rico, reports the death by yellow fever of the Governor-General of the Province. He adds, the yellow fever is much more fatal this season than for many years previous. Usually the disease has been confined to unacclimated Spanish residents just arrived, and to the troops, but for the past two months there have been very many fatal cases among the Creoles of the island, and within the last ten days there have been three deaths of Spanish officers, besides the Governor-General, holding high grades in the army. The epidemic, he says, is not confined to the Capital, but prevails with more or less fatality in the principal ports and towns of the whole province.

The Nature of Cholera and Precautions to be Observed in Time of Cholera.—The following rules drawn up by Drs. Koch, Skrzeczka, and von Pettenkofer, the Commission of experts appointed by the Prussian Board of Health, have just been officially promulgated:

Cholera is propagated by intercourse between people, and the infectious material clings, without exception, to men and the articles with which they come in immediate contact. The spread of the disease will be very greatly promoted, as experience has often shown, if, on its appearance in large places, the inhabitants take to flight and spread the germ of the disease far and near. This especially dangerous exodus of the population must be severely prohibited. Instead of thus leaving the infected place, it is easier to protect one's self from cholera by a proper mode of living and by observing the following precautionary measures, which cannot be done so well while travelling or away from home:

Every one, who would not endanger himself by receiving the germ of the disease into his house, should keep away from them those who come from stricken places. As soon as the first case of cholera appears in a place, the persons coming from that place must be considered as in all probability bringing the disease germ with them.

In time of cholera one should lead as regular a life as possible. Experience has shown that all troubles of digestion especially favor cholera. One should, therefore, particularly avoid whatever may cause digestive troubles, as excesses in eating and drinking, and the use of food not easily digested.

Everything which causes diarrhœa should be avoided. As soon as symptoms of diarrhœa appear a physician should be sent for.

No food should be used which comes from a house in which cholera rages. Food, the origin of which is uncertain, should only be used after being cooked. The use of uncooked milk is to be especially avoided.

All water which is fouled by human waste is to be strictly avoided. Water which comes from surface wells in inhabited places, is to be regarded with suspicion, as is also water from swamps, tanks, streams, and small rivers. Water is especially to be regarded as dangerous which has been in any way contaminated by cholera dejecta. It should be particularly observed, also, that water which is used for cleaning vessels and soiled clothes is not thrown into wells and watercourses, or in their vicinity. Since it is impossible to recognize contaminated water, only water which has been previously boiled should be used. These remarks are to be applied not only to water for drinking purposes, but to that which is used about the house for any purpose, since the infecting principle may be conveyed from the human body to the water used in the kitchen for washing and cooking food, and for laundry purposes.

People are especially warned against the opinion that the drinking water alone can act as the bearer of the infecting material, and that one may think himself completely guarded if unsuspicious or boiled water alone be used.

Every cholera patient may be considered a disease centre, and it is therefore advisable that the patient should not be cared for at home, but should be carried to a hospital. If this is not practicable, all unnecessary intercourse with the patient should be strictly avoided.

No one should visit a house in which there is cholera, unless his duty calls him there, nor such houses as were visited by the disease in former epidemics of cholera. Nor should one go to places, in time of cholera, in which large numbers of people are gathered (yearly at fairs, places of amusement, etc.).

No food or drink should be taken in rooms in which there are cholera patients. Clothes or linen soiled by discharges of cholera patients should be burned or boiled immediately, or placed in a 5 per cent. solution of carbolic acid for twenty-four hours. The discharges from cholera patients must, as soon as possible, be placed in vessels which contain a 5 per cent. solution of carbolic acid; and the vessels should be washed out with this solution when emptied. The discharges mixed with this solution may be thrown into necessaries or water-closets, but care must be taken that the discharges are not thrown into wells or into streams the water of which is used.

The floors and all articles soiled by cholera discharges must be cleaned with dry cloths or rags, which must then be burned or placed in a 5 per cent. solution of carbolic acid. Everything which comes in contact with the patient which cannot be destroyed or be disinfected by boiling, or in the carbolic solution, must be rendered harmless by means of hot steam in a special place of disinfection, or kept at least six days unused in a dry, airy place. The rooms in which there are cholera patients must, whenever possible, remain uninhabited for six days, and should be aired day and night during this time, so that they may be completely dried; and they should finally be dried by artificial heat. Those who come in contact with the patient, or with the beds and clothing, should thoroughly wash their hands with soap and water, and afterwards, when possible, wash them with a 5 per cent. solution of carbolic acid. This is especially necessary when they are soiled with the discharges from the patient. People are expressly warned against eating when the hands are unclean.

When death occurs the body, whenever possible, should be removed from the house and carried to a dead-house. If the washing of the body cannot be performed in the dead-house it should be omitted. The burial should be conducted in the simplest manner possible. There should be no attendance at the house of death, and people should not attend the funeral.

The clothing, linen, and other articles used by the

patient, or for the body, should not be sent away before being certainly disinfected. It is strongly advised that when such articles are received they be sent immediately to be disinfected. Laundries should only receive linen from cholera cases which has been previously disinfected. Other precautionary measures than those here given against cholera are unreliable, and all persons are warned against the use of so-called preventive medicines in time of cholera.—*Deutsche med. Wochensch.*, August 7, 1884.

Obituary Record.—Died, at Hartford, on August 21st, aged forty years, Charles Walter Chamberlain, M.D., Secretary of the State Board of Health of Connecticut. Dr. Chamberlain was educated in the arts at Brown University, and in medicine at the College of Physicians and Surgeons of New York, and graduated from the latter institution in 1871. He was for a number of years Examining Surgeon to the Pension Bureau, and was well known throughout the country as a distinguished sanitarian.

[OFFICIAL.]

War Department, Surgeon-General's Office,
Washington, D. C., August 20, 1884.

In announcing to the Officers of the Medical Department the death of Joseph Janvier Woodward, Surgeon and Brevet Lieutenant-Colonel, U. S. Army, which occurred near Philadelphia, Pa., August 17, 1884, the Surgeon-General wishes to offer his tribute of respect to the memory of the deceased, whose distinguished career and valuable services, for a period of twenty-three years, have shed lustre on the Corps, and for whose untimely loss feelings of profound regret will be shared alike by his comrades in arms and by the profession at large.

Doctor Woodward was born in Philadelphia, Pa., October 30, 1833, and was educated at the Central High School of that city, graduating with honor as Bachelor of Arts in 1850, and receiving the degree of Master of Arts from the same institution in 1855.

He graduated in medicine at the University of Pennsylvania, April, 1853; entered the Army as Assistant Surgeon, August 5, 1861; became Captain and Assistant Surgeon, July 28, 1866; Major and Surgeon, June 26, 1876. "For faithful and meritorious services during the War" he received the brevets of Captain, Major, and Lieutenant-Colonel, U. S. Army.

He was assigned to duty in this Office May 19, 1862, and from that date until the beginning of the illness which terminated in his death was intimately identified with its professional and scientific work.

While the valuable results of his life's labor are comprehended in a long list of miscellaneous publications, both professional and scientific, too familiar to the Corps to require individual mention, his greatest triumphs were won in the field of microscopical investigation in normal and pathological histology, and in his happy application of photo-micrography to the purposes of science. In these pursuits, he attained remarkable success, and achieved an enviable, world-wide reputation, leaving to science and medicine lessons of undoubted value and usefulness. Of his strictly professional work, the medical portion of the *Medical and Surgical History of the War of the Rebellion* was the crowning achievement. In the second part of this work, he developed the results of his careful investigations into the nature and pathology of the intestinal diseases which had proved so fatal in the late war. Here, also, he displayed his wonderful capacity for that minute and exhaustive research which forms so striking a feature of his writings.

As in the case of his colaborer, Otis, he yields to other hands the honor of completing his labors.

In addition to his engrossing professional duties, his restless activity of mind led him to seek recreation in his favorite studies, physics, art, and philosophy.

Endowed with a retentive memory, and of untiring industry, he acquired a vast store of information which he held available for use at will; fluent of speech, he took delight in the expression of his views and opinions both in social converse and in the arena of scientific debate.

His fund of knowledge, his strong convictions, his tenacity of opinion, and his quick perception made him a controversialist of no low order.

With such a record, it is needless to speak of his zeal, his ambition or his devotion to his profession, and especially to the reputation of the corps of which he was so bright an ornament.

Of a sensitive, highly strung, nervous organization, the confinement, anxiety, and labor to which he was subjected in his attendance upon the late President Garfield during his long illness, proved too much for a mind and body already overstrained by incessant labor, and precipitated the illness which finally terminated his life.

At the time of his death, Dr. Woodward was a member and Ex-President of the American Medical Association, a member and Ex-President of the Washington Philosophical Society, a member of the National Academy of Science, of the Association for the Advancement of Science, of the Academy of Natural Sciences of Philadelphia, and of the College of Physicians and Surgeons of Philadelphia. He was an honorary member of several American and foreign scientific, medical, and microscopical societies, and the recipient of many distinguished honors from learned bodies in this country and abroad.

R. Murray,
Surgeon-General, U.S.A.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 19 TO AUGUST 25, 1884.

Crampton, Louis W., *Captain and Assistant Surgeon.*—To report at Creedmoor, Long Island N. Y., not later than August 30th, as Competitor, and, in addition thereto, as Medical Officer of the Detachment of Competitors.—*S. O. 41, Division of the Atlantic*, August 20, 1884.

Cochran, J. J., *First Lieutenant and Assistant Surgeon.*—Assigned to duty at the Presidio of San Francisco, Cal.—*S. O. 81, Division of the Pacific*, August 16, 1884.

Wilson, Geo. F., *First Lieutenant and Assistant Surgeon.*—Relieved from duty at Fort Walla Walla, W. T., and to take station at Vancouver Barracks, W. T.—*S. O. 120, Department of the Columbia*, August 13, 1884.

Fisher, W. W. R., *First Lieutenant and Assistant Surgeon.*—When relieved by Assistant Surgeon Cochran to report, in person, to Commanding General Department of Arizona, for assignment to duty in that department.—*S. O. 81, C. S., Division of the Pacific.*

VOL. XLV. SATURDAY, SEPTEMBER 6, 1884. NO. 10.

ORIGINAL LECTURES.

AN ADDRESS ON ABDOMINAL SURGERY.

Delivered, August 25, 1884, before the Canadian Medical Association at its Annual Meeting in Montreal.

BY LAWSON TAIT, F.R.C.S.

SURGEON TO THE BIRMINGHAM AND MIDLAND HOSPITAL FOR WOMEN, BIRMINGHAM, ENGLAND.

MR. PRESIDENT AND GENTLEMEN: Every gardener knows that a plant long grown on the same soil rises or sinks, or somehow or other gets to a level from which it varies not so long as its conditions remain the same; and he knows as well, that if he takes that plant to a new soil which suits it, if he grows it under new conditions, its growth and change and development are practically endless. What we know of plants is, within limits, true of humanity, and if we require proof and illustration of this where need we go but to this endless continent of yours?

I am not at present concerned with natural boundaries created by languages which come from Sweden and Poland, Denmark and Scotland, Russia and Ireland, which temporarily limit intercourse between different peoples who perhaps settled here. Still less do I trouble about a line on the map which marks a practical republic on the south from a splendid democracy on the north. I have only to do with the great fact in human history—I think the greatest fact—that from out of the troubles and distresses of our eastern countries, or out of the countries oppressed by over-population, and still more by the effete policies of governments of past centuries, dislocated into modern life, from these there has come a great country and a great people, whose growth, change, and development promise to be practically endless.

Of my own country and of my own people you will not expect me, you would not wish me, to say anything disparaging. We are an old and respectable race, and by virtue of your descent you share that age, and you have brought over with you a full share of the respectability. But in transit you have lost that questionable virtue of extreme conservatism which we retain in every conceivable phase of life. We used to have mail-coaches protected against robbers by armed men, properly called guards, and we continue to call our railway servants guards, without the slightest reason save that they seem to be in some fashion successors to the blunderbuss-bearers of the eighteenth century. On the other hand, you very properly name the same officials conductors. We still build our railway carriages in compartments fitted to hold six people—confined boxes that are stuffy, inconvenient, wasteful of room, and dangerous—and we do this only because one hundred years ago we built our stage coaches on this pattern. Fifty years ago we thought, and we continue to think, that by sticking three of these old coaches end to end we must of necessity construct the best kind of vehicle for railway travelling. Untrammeled by tradition, you have contrived to build carriages far more convenient and suitable in every way. You have even sent them over to England for our use some ten years ago, but they had actually to be removed from some of our railways because the public would not use them.

I might gather further illustrations of that intensely conservative spirit which governs everything English. I might wander into the lines of religion and politics and hundreds of other sources, but I prefer to take one of which I can speak at length and in detail; one upon which I believe, if I read aright the compliment you pay me by asking me to appear here before you, I can speak with some authority.

In my early days the medical education of a British youth was not considered complete unless he had made a tour of the schools of France and Germany, and, like others, I felt of myself as was said of Proteus:

> "'Twould be a great impeachment to his age
> In having known no travel in his youth."

But I wish now that the time and money therein spent had been directed to the western instead of to the eastern continent; and I now venture to predict that ere long it will be to the medical schools of America rather than to those of Europe, that our students will travel, as did the apprentices of old before they settled down to the serious exercise of their craft.

For many years past I have been visited by numbers of my professional brethren from this side of the Atlantic, many of whom have settled down for days and weeks, and even months, to see my work. I have been overwhelmed by the kindliest invitations to visit this continent, but till now I have never ventured across. This delay is an instance of British conservatism, for it is very little the fashion amongst us to take long holidays. My American visitors have one and all impressed me with their possession of that feature of mind which in England I fear we do not possess—the power of judging any question solely upon its merits, and entirely apart from any prejudice, tradition, or personal bias. No matter how we may struggle against it, tradition rules all we do; we cannot throw off its shackles, and I am bound to plead guilty to this weakness myself perhaps as fully as any of my countrymen may be compelled to do. I may have broken free in some few places, but I know I am firmly bound in others, and my hope is that my visit to a freer country and a better climate may extend my mental vision.

To come to my intended illustration, let me briefly remind you of the early history of abdominal surgery. The first operation for the removal of an ovarian tumor was performed unwittingly in 1701, in a Scotch village, by Robert Houston, who began a tapping, and finished by making a successful ovariotomy. It was not until 1809, eighty-six years after Houston's case was published, that

his example was imitated, and even then it was not in Europe, but in the fresh soil of the backwoods of Kentucky that the young seedling obtained its first full growth, and from that time and from this country dates the history of abdominal surgery. But how slow the growth? In 1863, I heard my master, the Professor of Surgery in the University of Edinburgh, settle all this vast field of human progress in the few words, "abdominal surgery is abominable surgery." Syme, the greatest surgeon by far with whom I have ever come in contact, shared the views of his colleague in this matter, and I fear that in both of them the sentiments originated far less in the merits of the question before them than in their mutual dislike (almost the only sentiment they had in common) of John Lizars, who, having read MacDowell's manuscript when it was sent to John Bell, was immensely struck by the success of the heroic Kentuckian, and was desirous of following his brilliant example. Most unfortunately for humanity, the success of Lizars was of a very doubtful kind, and abdominal surgery had to wait for the advent of Dr. Charles Clay and Mr. Isaac Baker Brown. The story of the latter brilliant and unfortunate surgeon is now a thrice-told tale, and I can only repeat here what I have said at length elsewhere, that his disastrous downfall was a misfortune for humanity, delaying, as it did, the progress of abdominal surgery for fully a quarter of a century. The whole question of this progress lay in the peculiarly narrow issue as to whether the pedicles of ovarian tumors should be dealt with inside the peritoneum or outside it. Here again the new country was first in the race, for between 1820 and 1830 the decision in favor of the intraperitoneal treatment was given in America in such a way that the question ought never to have been reopened. The arbitrament of abdominal surgery between 1866 and 1876 was left in the hands of a man still living, and he carried through his practice a mortality so heavy as to be absolutely prohibitive of fresh enterprise. Mr. Baker Brown left off practice in 1866, with a mortality of ten per cent. with the cautery; whilst, after operating on a thousand cases, Sir Spencer Wells had a mortality of twelve per cent. with the ligature in the last hundred; and over the whole thousand the mortality was exactly twenty-five per cent. With such results as these, the marvel is not that the conservative surgeons cried out twenty years ago that the craft was in danger, but that the removal of ovarian tumors ever became an accepted operation at all.

As I have said over and over again, and as I shall never tire of saying, to Keith is due the whole credit of the modern development of abdominal surgery, and it has ever seemed to me specially hard that while wealth and a title have been the lot of the man who had done nothing but obstruct progress, to the author of our present proud position nothing has come save a good deal of misrepresentation and abuse.

In 1878, the doctrines and practice of Lister, after twelve years of preaching on the part of their author, had penetrated to London, and were taken up by Sir Spencer Wells and his assistants. I had practised all the details in their ever-varying form, as recommended by Mr. Lister, from 1866 onwards, and gave them up, one after the other, as I found they disappointed and hindered me. Finally, I gave the spray and its adjuncts a long and complete trial, a trial far more careful in its details than anything I ever saw elsewhere, this trial extending over three years. I have published in detail the disastrous results of this experiment, and at last I gave up all these unnecessary dangers, and since January 7, 1881, my practice has been entirely free from all these details. Since then my example has been followed by Dr. Keith, Dr. Bantock, and by my colleague, Dr. Savage, and the only surgeon now who uses the Listerian details for abdominal surgery is Mr. Knowsley Thornton. He still claims for Listerism the most of our present progress, in spite of the fact that Keith, Bantock, Savage, and myself have all far better results without Listerism than Mr. Thornton has with it. Mr. Thornton went so far recently, in a communication to Dr. Bigelow, which that gentleman published, as to say that his (Mr. Thornton's) bad results in hysterectomy were due to the fact that in this operation the Listerian details could not be effectually applied. But the facts of the practices of Mr. Thornton and Dr. Bantock, the two surgeons to the Samaritan Hospital, settle the question when they are contrasted. Mr. Thornton uses the Listerian details for hysterectomy as well as he can, and in twelve cases he has had five deaths, while Dr. Bantock does not use the Listerian details at all, and in twenty-two cases he has had only two deaths. The explanation of the difference will be evident to every one who has seen both of these gentlemen operate. To see Dr. Bantock do a hysterectomy is a lesson in surgery, and one from which I learnt a great deal.

To see my own work, I have been honored with the visits of a large number of surgeons from this continent, some of whom I see here now. I believe they one and all came with the belief that they would find I had some secret antiseptic agent, the use of which was the explanation of my success. If I have such an agent, it must be of universal existence in nature, for I have made some of my visitors take water from the tap and put it into the basins for the sponges and over the instruments and into the abdomen. I have made them drink it, and have offered it to them for analysis, and so far, I have not been detected in any exercise of magic. My visitors always ask to what I attribute my success, and I answer that I cannot tell. They frequently suggest that it is climate, and my answer is that our climate is the most variable and uncertain, the worst in the world. It is not fresh air, for the great majority of my operations, and always the worst, are done right in the middle of a large manufacturing town.

If I may formulate my own answers, they would be briefly to this effect. I have given up my life to this work and I engage in no other kind of practice; therefore, I have a constant weekly experience of five or six of these operations, sometimes as many as eight or ten. I pay the most minute attention to every detail, and maintain an absolute rule of iron over my nurses and my patients. I will not, if I can avoid it, operate in a private house, for there I have no control over either nurse or patient, still less over foolish friends. I can best illustrate the extent to which I carry discipline by telling an incident which occurred recently, of a kind of which I have had a few, but not many experiences. For my private hospital I have a rule that when a patient is admitted she must go to bed immediately. A lady with an ovarian tumor arrived after a journey of some hundreds of miles, and was asked by the nurse

told off for her, to go to bed. She said she would not do so till she had seen me. The nurse assured her that I would not come near her till she was in bed. The patient remained obstinate, and I sent a message to her that she must either go to bed or go home again, and she elected to do the latter, with much satisfaction to myself. She doubtless thought, and you may think, the rule in question is an absurd one, but the absurdity is only on the surface. It is a test of the patient's obedience and confidence in me, and I know very well that with a patient who begins by disputing my orders and doubting the wisdom of my directions I never could get on, and, therefore, it is better for both that we should have an early parting. My nurses I always train myself; in fact, I will not have one who has had previous experience, for I know very well that such a woman will inevitably, to save herself trouble, do something in a way she has seen done elsewhere, and probably for some purpose altogether foreign to my intention, and will therefore become to me a source of danger and annoyance.

Finally, I give great personal attention to cleanliness in every detail of my work. I trust no nurses or servants without overlooking; and I am constantly and at unexpected times turning up carpets, taking down shelves, and routing out cupboards. In this way, and by a process of weeding, I have obtained a large staff of good servants, and have founded a large establishment in which every available precaution is secured. I can give no other reasons than these for my success, and probably they will commend themselves to you.

There are, however, some causes intrinsic to the work itself, from which the success has sprung to a large extent, of which a few words may here be said with advantage. The first, of course, is the discontinuance of the clamp, of which I have said a great deal elsewhere. Whatever Sir Spencer Wells may say to the contrary, neither with nor without Listerism would anybody go back to the clamp. But the curious thing is that there are recent experiences in hysterectomy which would make it appear that it is not so much the clamp which has been to blame as Sir Spencer Wells's method of using it. Hysterectomy must always be a more serious operation than ovariotomy. Yet Dr. Bantock is now obtaining better results in removing the uterus with a clamp than Sir Spencer Wells ever got in removing simple ovarian tumors; and we must bear in mind that Sir Spencer always insisted that he used the clamp for his simplest cases—cases with long and easy pedicles.

Puzzling over the mysterious and startling contrast, I went to see Dr. Bantock operate, and amongst other things I found that he had given up using perchloride of iron for the purpose of tanning the stump. I asked him why he had done so, and he told me he was quite sure the use of the perchloride of iron had added greatly to the mortality of the clamp, because with a thick pedicle secured by the clamp it is impossible to close accurately the abdominal wound and prevent draining into the cavity. I did not at once accept Dr. Bantock's explanation, but I determined to use the perchloride of iron no more. Like everybody else, I was prejudiced in favor of the statement made by Sir Spencer Wells—that a putrefying stump would poison the wound, and therefore I could not make up my mind to allow it to remain without some kind of interference. Years ago, in blaming the clamp for our high mortality, I had pointed out the likelihood of this incomplete closure as being one of the causes, if not the chief cause of death. But I certainly did not suspect the perchloride of iron as being the fatal agent. A few days after my interview with Dr. Bantock, I had to perform a hysterectomy, and I dressed the stump with crystals of thymol. The patient died of peritonitis on the fourth day, and that the thymol had trickled into her peritoneum and had poisoned her we had proof enough. Since then, I have done hysterectomy twice without dressing the stump at all, and the patients are at present perfectly well. It will be curious, indeed, and no less instructive, if we find that Dr. Bantock is right, and that the use of perchloride of iron—the only contribution Sir Spencer Wells has ever made to abdominal surgery—should turn out to be the cause of his tremendous mortality. In any case, it is a remarkable example of how absurdly we are all governed by *à priori* statements—statements absolutely void of any arguments in support of them, but having been made by some one with an authoritative name and position, are accepted without doubt. If Dr. Bantock's brilliant results are obtained by others in the same way, then we have been going on destroying women with perchloride of iron merely because Sir Spencer Wells said we should use it.

As the whole aspect of abdominal surgery is at the present moment controversial, as the progress and practice of this part of our art form the chief objects of my life, you need not be surprised if I have made this address somewhat of a polemic. The greatness of the opportunity, the fact that an address given to you will be read where mere utterances of mine would be passed by, obliged me to take advantage of the opportunity you have given me to carry on the discussion. The course of this particular line of work has, as you know, taken a sudden bound of activity within the last few years, and the reason is a very simple one. The immense success in the removal of ovarian tumors such as threatened to destroy life with absolute certainty which followed the efforts of Mr. Baker Brown and Dr. Keith, led some of us—myself especially—to venture into regions where life was not necessarily, or, at least, not apparently threatened, but where suffering was persistent and incurable, and where the sufferers had been proved by protracted trial to be outside the powers of ordinary remedial measures. In a recent paper by Sir Spencer Wells, published in the *Medical Times and Gazette*, the argument is completely dislocated, and put in an altogether *ὕστερον πρότερον* fashion, and therefore I must here give a little attention to the views of that writer. He tells us that ovariotomy had at one time a mortality of seventy or eighty per cent., but I know not whence he gets his information. Doubtless it would be possible to find occasional examples of surgeons with limited experience having such a heavy death-rate, but such an isolated case would not yield a fair statement of the facts. I read a few months ago in an American medical journal that in Italy there had been one hundred cases operated upon, with sixty-three deaths; and the newspaper recorded the fact that "thirty-four surgeons were engaged in the sanguinary work." But when the work of men who can be called ovariotomists is examined, no such results are seen. Charles Clay was the first man who did an ovariotomy in England,

and his maximum of mortality in his first series of cases was forty per cent., but it speedily fell to twenty-five per cent., and this is very much what has been recorded by Sir Spencer Wells of his own practice.

In the paper of which I am speaking, Sir Spencer goes on to say that "afterwards when the strictest hygienic precautions were supplemented by antiseptics and improvements in operative details were generally adopted, success became so great that ovariotomy not only took its stand as by far the most successful of any capital operation in surgery, but the risk attending it in a favorable case could truly be calculated as little, if at all, greater than that attending any case of natural childbirth, and, as a necessary consequence, early operations could be advised with less hesitation." The statements in this sentence are wrong from beginning to end. In the first place, the mortality of ovariotomy in the hands of Keith and myself still remains at or about three per cent., and we have shown the least mortality yet available. The mortality of natural labor, on the other hand, is certainly not .25 per cent. The statement that diminished mortality has lead to early operations should be exactly reversed, for it is the early removal of tumors and the discontinuance of tapping which have largely contributed to our present splendid results. Sir Spencer Wells's teaching inculcated the practice of tapping and its repetition until the patient was within measurable distance of the grave, but his successors have reversed all this with infinite advantage to their patients, and we now look upon tapping as a sort of surgical crime. This material alteration in practice led us step by step in the direction I have previously indicated, and we began to discuss the greater advantage to which I have just alluded. Every specialist is familiar with a large class of miserable women who wander about from hospital to hospital or from consulting-room to consulting-room, seeking relief from their ailments unavailingly.

Let me take the first class to which Sir Spencer Wells alludes in his recent paper—cases of uterine myoma. There can be no doubt that there are hundreds of uterine tumors that give no trouble at all, but these are not the cases that come to us. If a woman has no pelvic trouble she does not present herself to the gynecologist, and if she has a uterine tumor which gives rise to no symptoms, that tumor of course remains undiscovered; but when she suffers from distress occasioned by pressure on viscera from severe hemorrhage or increasing size, she comes to us and asks for advice. Suppose we find her to be suffering from a uterine myoma, what are we to do? The answer to this question is like the answer to every other of a similar kind: each patient must be advised according to the circumstances of her case. If the tumor is small and the woman comparatively near her climacteric, and the hemorrhage such as can be moderated by a rest in bed and the use of ergot, then she should be advised to let the tumor alone. But if the woman be not near her climacteric, and the hemorrhage does not yield to treatment—especially if after a fair trial of treatment the tumor is found to be actively going on—then surgical treatment is demanded.

Of course, every practitioner of medicine and surgery does and always must carry on his work in his own way, and there can be no doubt that within certain limits the measure of his success stamps the rightness or the wrongness of his methods. James Syme used to teach us that there were three methods to conduct our professional business, but that there was only one way to real success. He said there were three interests involved. First in order, that of the patient; second, that of the professional colleague; and, third, that of the practitioner himself. Syme insisted that the several interests should be rigidly kept in the order in which he placed them, or things would be sure to go wrong. I have never heard sounder advice, and have never lost sight of it, and, so far as within me lay, I have striven to follow it. In the proposals of a new proceeding, two dangers clearly occur: the first, that of the enthusiastic upholder of the novelty, who may be disposed to run too fast in the new line; the second is that of the obstructive, who, merely a believer in the times that are past, can see no possibility of their improvement. The remedy for the first danger is a wholesome scepticism leading into just and careful criticism; the remedy for the second is more difficult, for it involves a patient endurance of much misrepresentation and a protracted combat upon the points of criticism which have no weight in themselves, and have an importance gained only by persistent reiteration. In the line of practice of which I am about to speak, the point most persistently urged against our new line of practice is that unnecessary operations are performed. Now this is an argument which it is extremely difficult to argue upon, because those who speak on the two sides of the question start from altogether different standpoints. Those of a past generation, like Sir Spencer Wells, apparently regard it as justifiable to perform operations in this department of abdominal surgery only when life is pronouncedly in danger; whereas, on the contrary, we of the younger school believe we are justified in extending our practice for the relief of suffering, and we regard this as a higher function than that of the mere saving of life. To end the discussion of this point I would point out that our critics endeavor to apply an arbitrary rule for the repression of abdominal surgery which has never yet been applied in any other department of the art. Let me ask, if we find a man suffering slightly with the early symptoms of a small calculus, do we not at once proceed to relieve him by removing it from his bladder? In fact, in the domain of what is called general surgery, has it not become an established practice to perform operations which are accompanied by very considerable risk of life merely for the rectification of deformities, such as bow-leg and knock-knee, which have not the remotest risk of life attached to them and which involve no kind of suffering? The ultimate court of appeal therefore comes to be the patient's own decision, and I do not find that patients prefer to go on suffering pain and the disabling effects of profuse loss of blood rather than submit to a surgical operation, the details and effects and ascertained risks of which are completely and candidly placed before them.

In the treatment of uterine myoma two alternatives occur, and these are both the subjects of very hot discussion on my own side of the Atlantic; they are removal of the uterine appendages and removal of the uterine tumor itself by the so-called supravaginal hysterectomy.

No one in Europe, at least only one authority so far

as I know of any importance, doubts that removal of the uterine appendages arrests menstruation completely in the great majority of instances, arrests the growth of uterine myoma generally, causes it to shrivel up, and in many instances actually to disappear. Mr. Knowsley Thornton, Dr. Savage, Professor Hegar, myself, and others have reported numerous cases in detail. I have published a long series in The American Journal of the Medical Sciences for January, 1882, but Sir Spencer Wells dismisses us all in the brief sentence, "Vague, unsupported assertions have little influence upon the opinion of a thoughtful or a sceptical profession." Sir Spencer Wells must pass his retirement in some other way than in perusing the modern literature of his specialty and therefore his criticism need hardly engage our attention seriously.

The great majority of cases of uterine myoma which come to us for surgical treatment, can be quite satisfactorily dealt with by removal of the appendages, and it is an operation having a small and a steadily diminishing mortality. The arguments used against it are first that of its mortality, but this mortality is the inevitable death-rate of early work, and it is, therefore, not a permanent objection. It was an objection urged twenty-five years ago against ovariotomy, but against that operation it no longer holds good. The second objection is that myoma itself is not a fatal disease, but this is not an argument in harmony with my own experience. Even if it were a just one, however, it is admirably met by a plea entered at Ryde, in the discussion of my paper on the subject, to the effect that it is to the rights and relief of the majority that we must have regard, and that the function of our profession does not end with the saving of life, but it is chiefly that of relieving suffering.

Two other objections have been urged generally against the removal of uterine appendages that it sterilizes the patient and destroys their sexual appetites. Of course, a woman is completely sterilized by a uterine myoma ninety-nine times out of one hundred, so that the process of complete destruction of fertility is a matter of little moment. The other objection has been shown to be perfectly groundless, and even if it were not so, it could hardly be urged on the ground of morality that a woman should go on suffering because she ought not to suffer any diminution of that animal propensity which it is the chief object of the higher life of all religious culture to subject, and the subjection of which forms for all creatures the greatest difficulty of existence.

There are cases of myoma demanding surgical treatment upon which removal of the uterine appendages seems to exercise no satisfactory influence. Mr. Knowsley Thornton has made a very valuable suggestion, one which certainly deserves very careful consideration, that all cases of myoma requiring interference should first be subjected to removal of the uterine appendages and then to subsequent operation if it should be found necessary. The only objection to this that I can offer, at present, is an incomplete one. I have pretty well satisfied myself that there is one form of myoma on which removal of the uterine appendages exercises no control, a variety which I have named the soft œdematous myoma. But it is not easy to recognize this form of myoma until it has been removed. Again there are a few cases, very few I have found them to be, in which the appendages cannot be removed, and we must proceed to hysterectomy. Finally, the removal of uterine tumors has had such brilliant results in Bantock's hands, that I am in hope that a new era for hysterectomy has been opened out.

Another class of cases wandering about seeking relief, are those upon which I have operated in large numbers, and have found chronic and incurable disease of the appendages in the form of chronic inflammation of the ovary, chronic inflammation and occlusion of the tubes, these latter being occluded and distended by serum, pus, or blood. When I first published my work on this subject, there was, of course, a large amount of incredulity expressed about it, and this incredulity was not much lessened by the exhibition of a large number of specimens at various Societies, and their permanent exhibition in the museums of the Colleges of Surgeons. Many, particularly amongst my metropolitan brethren, loudly asserted that there were no such diseases, and Sir Spencer Wells stated, at the International Medical Congress in London, that if such diseases did occur, they must all go to Birmingham. But Dr. Kingston Fowler has shown not only that they exist in London, but that they are far more fatal than I had any idea of, and that they have been and are overlooked and misunderstood in the metropolis just as they were overlooked and misunderstood in my own practice previous to 1878. Concerning this incredulity, please distinctly understand that I do not blame anyone for it; it is a necessary part of all human progress. I do not even blame my metropolitan brethren, as they seem to think I do, for not discovering these cases and properly treating them. That is the fault of the mechanical school of gynecology, established by Simpson, and which exercises a far too great influence over this department of our art. During the last twenty years, displacements have had a great run, just as before that time everything was put down to ulceration, and no man considered himself properly armed for the treatment of disease unless he carried a speculum and a caustic stick about with him in his gig. The mechanical school revels in the sound and the pessary, both useful enough in their proper places, but when misused are capable of endless mischief, for many of the so-called displacements are now known to be constituted by chronically inflamed and adherent tubes and ovaries, capable of relief only by their removal.

You will ask me at starting, to tell you how these diseases may be recognized, and I have to answer that their diagnosis cannot now, and probably never may be a matter of certainty. They begin generally in some acute attack of pelvic inflammation, from which the patient dates all her troubles, and when you get such a distinct history you ought at once to be on your guard. This illness may have arisen, for instance, in a clearly defined and confessed attack of gonorrhœa, or it may be an attack of pelvic perimetritis occurring after a miscarriage or a labor, or it may have arisen in one of the exanthematic fevers or a simple cold. In some of the cases, however, you get no clear starting-point in the history, and then the diagnosis is generally more difficult. The symptoms are usually precise enough, yet unfortunately none of them is peculiar to the condition of which we are speaking. Pain is, of course, a

leading feature, as indeed it is rarely without pain as a chief incentive that patients consult us at all. This pain is complained of as being constantly present, greatly aggravated by walking and becoming intense for some hours or days before the period and lasting throughout its continuance. Menstruation is usually too frequent and too profuse. In the great majority of the cases the uterus is somewhat fixed, and a tender mass can be felt at one or other side of it, perhaps on both sides, and behind it. When the tubes and ovaries are down behind the uterus and adherent there, and this is by far the most common condition, the diagnosis to a beginner is extremely difficult. Nothing looks more certain and easy than the diagnosis of subinvolution and retroflexion, and without further consideration a pessary is introduced, with no other result than that of aggravating the patient's sufferings; in fact, I may say that at this point her troubles will begin to be serious, and she will wander about collecting various kinds of instruments from various practitioners, until she ends either a helpless or hopeless invalid, or dies from an attack of acute peritonitis.

In some of my most marked and most successful cases, there have been no physical signs at all, and I have felt myself reluctantly justified in interfering only by the manifest reality of the patient's sufferings.

Here let me just say a word about the much discussed question of subjective symptoms. Everybody has heard of the celebrated story told of Liston, that a hysterical girl persuaded him to remove a healthy limb for supposed disease of the knee-joint; but is there any other story of the kind known? If there is, I have not come across it. We certainly do meet with women who will tell incredible stories about their sufferings, but the stories are so inconsequent and contradictory that there is no difficulty in discounting them. Besides, they have no support from the presence of corresponding physical signs. A woman whose sufferings are real has a sequent narrative and will submit to treatment, while the woman who is a humbug flies off at a tangent the moment a suggestion is made that she should submit to an operation in which she risks her life. I have never yet known a woman submit to an abdominal section in whom I did not find abundant justification for its performance, even in cases in which I had been extremely doubtful about its real necessity before I undertook it. I have known many patients to whom I have made the proposal as a test of their reality, and who, much to my satisfaction, have speedily taken themselves off to some other practitioner.

As to the details of the operations in these cases, I have no time here to speak; indeed, I could deal with them satisfactorily only in a series of lectures. Suffice it to say, that the operations are very difficult, for the structures are always extremely adherent, and the operator has nothing to guide him save the erudition of his touch. Concerning the cases of occluded and distended tubes, some of my critics have suggested, without any experience, that something short of abdominal section might suffice for their successful treatment, such as tapping the tubes from the vagina; but a trial of this proceeding long ago satisfied me of its impracticability and its uselessness, and my growing experience constantly confirms me in the conclusion that we have no alternative.

I am often asked concerning the subsequent history of these cases, and I am able to say from the published details, that the great majority of them are relieved at once and completely by the operation. In some of them there remains a tenderness of the stumps, lasting for some months. In four very bad cases fecal fistulæ had formed, and in two the sinuses have healed and the patients are perfectly well. In the third case the fistula opens still at occasional intervals, and in the fourth case, by far the worst I have ever had, the patient being literally at death's door when the operation was performed, the fistula still remains open, some twelve months after the operation, and even here her health has so greatly improved that I am hopeful of its permanent closure in time.

I have occupied your time already at too great length, and yet have left myself no time whatever to speak of a great variety of topics within the limits of the subject of my address of which I fain would have spoken—subjects entirely novel, and full of the deepest interest alike to the practical surgeon and to him who takes but an interest of a literary kind in the progress of our art. In fact, it is a matter of regret to me that I cannot address such an audience as this in a series of lectures rather than in an address which must necessarily be brief. It is one of the great defects of a position such as I hold—a defect inherent in a special line of practice—that it practically shuts out its follower from any chance of being a teacher. Besides, I feel strongly this as acting to my own prejudice, and I am certain it is a misfortune that those who, like myself, are very largely engaged in work strictly limited to a department can never communicate as successfully the results of their experience as can those who are engaged in teaching. I regret, therefore, that I must pass over without mention the important field of new work which has been opened up within the last few years in the surgical treatment of the liver, spleen, kidney, and intestines. I cannot even stop to speak of many other, less striking, but no less important, subjects, such as the treatment of pelvic abscesses by abdominal section and drainage, though all these are of less importance, in so far that they excite but little hostility; and what I have to say to you further I purpose to limit to a brief discussion of a proposal, made by Dr. Robert Battey, for the production artificially of the menopause for the purpose of indirectly benefiting patients suffering from conditions more or less neurotic, the symptoms of which are apparently influenced by the recurrence of menstruation.

It must be perfectly clear to the most casual observer that this is a field of an extremely ill-defined character, one which at first sight offers but very intangible prospects of success, and in which the indications even of success must be very vague and indefinite. There can be no doubt that a large number of women suffer in such a way as to make it perfectly clear that if they were relieved from recurrent menstruation they would be improved; but there can be no doubt that the application of this idea—in itself a brilliant one—requires the utmost care. I have no sympathy with stupid obstructionists who, because they scent danger in the air, would absolutely prohibit its application; but I have sufficient regard for the expression of every kind of professional opinion to recognize the necessity for the full exercise of caution.

When the proposal was first made, I recognized this so fully that I selected for whatever experiments I should make in this direction, a disease concerning the reality of which there could be no doubt whatever—I mean epilepsy. It is a perfectly easy thing to recognize by two facts alone any case of genuine epilepsy from mere hysterical imitation. It was, I think, Dr. John Hughes Bennett who clearly established the facts that none but the true epileptics ever seriously hurt themselves during the attacks, and that after the fits are over the epileptic is always somnolent. It is certainly the case that in a large number of cases of epilepsy in women the incidence of the disease is concurrent with menstruation. It is also true that every epileptic woman whose case I have investigated is worse during the menstrual week than at any other time. In some cases, the epilepsy is absolutely limited to those days of the month during which the menstrual flow is in existence. It was, therefore, a perfectly easy thing to select a number of cases in which the experiment of Battey's operation seemed capable of justification.[1] For the purpose of trying the experiment, I selected six cases, and to these I have absolutely limited its application, though from the number of patients who have been sent to me for the specific purpose of having the operation performed, I suppose I might have been able, by this time, to have placed several scores of attempts on record. The reason of my careful restriction has been that I do not care to prejudice the results of my other work by complicating it with what seemed to me a doubtful kind of proceeding; but all my care has been to some extent fruitless, for I have been persistently charged by a certain class of writers with having performed a large number of useless and unnecessary operations in removing normal ovaries in women suffering from nervous disorders. Indeed, so late as July 5th last, Sir Spencer Wells wrote the following sentences, which, though they may have been intended for some one else, I cannot help but suspect were levelled at me. They run as follows: "Just now something more than a word of caution against rash, dangerous, and unnecessary operations is called for. We are startled by the reports of the removal of normal ovaries of young women suffering from nervous disorders, which may be exaggerated or imaginary; and it is to be feared that our professional honor is at stake, and that abdominal surgery, in its latest developments, is open to the denunciation hurled against the early ovariotomists; and that, with more reason than in 1850, Lawrence's question must be repeated, whether such operations can be encouraged and continued without danger to the character of the profession; and West's assertion that the fundamental principle of medical morality is outraged, cannot now be satisfactorily refuted."

Though I am fairly familiar with the literature of abdominal surgery during the last ten years, I am absolutely ignorant of anything which can possibly justify such ridiculous exaggeration. I have publicly challenged Sir Spencer Wells to indicate the proceedings to which he alludes, and to produce the evidence upon which he bases his charges; but up to the moment of my leaving England he had not taken up the gauntlet. It is a somewhat remarkable fact that in another journal, in the same month, the same writer actually pleaded in favor of the removal of tubercular lungs; that such an operation would be justifiable if it saved one patient in twenty of those operated upon, and it seems to me absolutely impossible to reconcile such a recommendation with the denunciation I have just read.

So far as my own work in Battey's operation is concerned, in not a single one of the six patients operated upon were the uterine appendages normal. In two of them, typical examples of cirrhosis, the pathological anatomy was carefully investigated by independent observers, one of whom was the well-known and accomplished pathologist, Mr. Alban Doran, by whom the appearances were fully described and figured in the *British Medical Journal* for Nov. 8, 1879. The results of these operations, in the first place, were that all the patients made easy and uninterrupted recoveries; the operations were performed after the most careful consultation, and with the full cognizance on the part of the patients and their friends of the results which were certain, and the entirely speculative nature of those it was hoped would be obtained. As I have already published the cases in detail, with the exception of the last, which was performed only a few weeks ago, I need not here repeat them save in general terms, and that is to the effect that in two cases the results are such as to justify completely the proceedings. In both of these the disease before the operation was so intense that it was threatening life, but now it is almost entirely subdued, and the health of the patients has been enormously improved. In one case the disease was entirely arrested for a year and a half, and though it is now returning, the patient has been transformed from a wretchedly feeble, anæmic, and broken-down girl into a healthy and robust woman, although affected by epilepsy almost as badly as before. In two others the disease has been greatly modified, and the health of the patients has been immensely benefited.

From this brief record, it is quite a matter open for discussion as to whether the continuance of the proceeding can be recommended, and I am bound to say that I have not myself a very strong opinion in the affirmative: but I think if I had a daughter with feeble health, the result of pronounced menstrual epilepsy, I think I would advise her to have the operation performed. From what I have seen of it myself, I think there can hardly be any risk about it, and if performed with the precautions I have indicated, I do not think it can be brought under the sweeping category of Sir Spencer Wells, as being either rash, dangerous, or unnecessary.

There is another argument, and I think one that may be said to have some moral force, in that, as it will assist in the prevention of the distinctly pronounced hereditary

[1] Dr. Thallon, of New York, has lately published an article in Seguin's *Archives*, which is an admirable illustration of the Teutonic process of elaborating a camel from the inner consciousness of the writer. Dr. Thallon seems never to have read what either Dr. Battey or I have written on this subject, and he has created a new term, against which I desire to enter a vigorous protest. He speaks of the "Battey-Tait" operation. There is no such thing. Dr. Battey's proposal is as different in its purpose, in its details, and in its application from my own as lithotomy and amputation. I need not enter into the further details of Dr. Thallon's criticism and conclusions, as they are reached solely by the utter absence of experience of the matters on which he has chosen to write.

tendency of the disease, we should at least hesitate before we entirely condemn it. Certainly a great deal more can be said for it than for the proposal of pneumonotomy for phthisis, on the assumption that the removal of a lung would only save one patient out of twenty. Removal of the uterine appendages for epilepsy would probably not kill more than one per cent.; and I am certain it would materially relieve fifty per cent.; it would improve the health of the great majority of patients, and I do not think it would make any of them worse than they were before the operation. I am hopeful, therefore, that the verdict of professional opinion will not be adverse to a fair and reasonable trial of Dr. Battey's proposal, and I trust that the freedom from the prejudice and shackles of tradition which we find on this side of the Atlantic will secure for it a fair field.

And now, in conclusion, let me thank you most sincerely; and not only you, but many other professional bodies, and large numbers of professional friends, for the kindly, I may say overwhelming reception I have met with at your hands. For many months before I left home there was hardly a mail arrived which did not bring me invitations of public or private hospitality, and these brought forth feelings of regret that my stay on this continent could not be prolonged for as many months as it will have to be limited to days. One thing I recognize in this above all others, and it is that you are treating me not on my own merits, but as a representative of a large body of men in my own country, to whom you have owed much in the past, and with whom you are in the present united in a common bond of brotherhood and community of sacred purpose. For the future, I predict that the unity and the union will be more and more complete. If it should be in the mind of any that in what I have said I have been lacking in detail, let me say again that the theme you gave me was far too wide to be satisfactorily and completely dealt with in one address. If, on the other hand, I should be adversely criticised as having spoken strongly upon matters in dispute, let my apology be that I have worked hard and long and earnestly in the field I have undertaken, and that no man can feel strongly without infusing into his words some tincture of the thoughts that govern his actions.

MEDICAL REPORT ON THE CONDITION OF THE SURVIVORS OF THE GREELY PARTY, WHEN RESCUED BY THE RELIEF SQUADRON.[1]

BY EDWARD H. GREEN, M.D.,
SURGEON OF THE U. S. S. THETIS, OF THE GREELY RELIEF SQUADRON.

As a preliminary to the medical history of the cases of the survivors of the Lady Franklin Bay Expedition, it is well to give a brief *résumé* of their mode of life at Camp Clay, their quarters, rations, etc., so as better to appreciate the condition in which they were found.

On September 29, 1883, Lieutenant Greely landed with his party at Baird Inlet after thirty days' exposure drifting on an ice-floe; the record left at that time stated the *party was all well*. Having sent an advance detachment ahead, which found and reported that a *cache* of provisions existed at Cape Sabine (fifteen miles further to the northward than he was at this time), it was deemed expedient to move the whole command up to that neighborhood rather than send for the provisions, and winter at Baird Inlet. Finally, on October 25th, they moved around to a point between Cape Sabine and Cocked Hat Island (lat. 78° 45′ N., long. 74° 15′ W.); the site of their winter-quarters was sheltered between high ridges of mountains, which screened them in a measure from the northerly and southerly winds. A glacier was situated at the foot of the mountains on either side of them about a mile distant. They constructed a house of loose rock and moss, the walls being three feet in thickness. The roofing consisted of old canvas stretched over a boat; the dimensions of the house were 25 feet long by 17 feet wide by 4 feet high, making a cubic air-space of 1700 feet, in this the twenty-five members of the party lived all winter, having a cubic air allowance of about seventy feet for each man. The whole party could barely squeeze in and lie at length, two or three being obliged to occupy the same sleeping-bag; the effect of this diminished air-space will be seen later on. Their hut was but 100 yards removed from the ice-foot of the sound, and 200 yards to the south of them was an artificial lake, from which they drew their water supply by melting up ice; as the sea water strained into this lake, they were drinking brackish water all the while.

On November 1, 1883, Lieut. Greely took a careful account of his stock of provisions, and found there was but a whole ration for each man (estimated as an army ration, about forty-six ounces of solid food per diem) for forty days. Doctor Pavy and he advised together, and it was with some reluctance that they determined to divide up the rations so as to make them last until March 1, putting aside from time to time, so that at the end they would still have ten days' supplies left with which to attempt the trip to Littleton Island, if the Straits were frozen over. Doctor Pavy did not think the party could exist on the ration during the winter, but the common voice was to make it go as far as it would; so each man was given the following daily allowance:

Meat and blubber, . . .	4.33 ozs.
Bread and dog biscuit, . .	6.5 "
Canned vegetables and rice, .	1.4 "
Butter and lard, ...	0.75 "
Soup and beef extract, . .	0.90 "
Berries, pickles, raisins, and milk,	1. "

Making the daily allowance for the four months 14.88 ozs. During the winter the following amount of game was secured, which added to their stores: 2 seals, yielding about 120 lbs. of meat, one bear, yielding 300 lbs. of meat, 8 foxes (4 lbs. each), and 60 dovekies (uria brunnichii), a small bird, weighing about a pound.

March 1 found the party intact, with the exception of Sergt. Cross, who died in January with well-

[1] This paper was specially prepared for THE MEDICAL NEWS, to which it was forwarded by Surgeon Green, through the Bureau of Medicine and Surgery of the Navy Department.

marked scorbutic symptoms—the only case of pronounced scurvy that developed—and Hans, their Esquimaux hunter, who was lost in his boat while hunting seals, early in February. The Straits having been kept open during the winter by a succession of violent gales, the attempt to cross to Littleton Island had to be abandoned, and their ration was still further reduced to the following allowance: meat 6.8 ozs., bread and dog biscuit 3.2 ozs. The rest of the stores having been exhausted, the remaining supplies were divided up so as to last until May 12th. The sun had returned by this time, after an absence of one hundred and twenty-eight days, and those employed as hunters caught the shrimp (crangonidæ), a small crustacea, one-eighth to one-fourth of an inch long, consisting of about four-fifths shell and one-fifth meat. From 1 to 3 ozs. of these a day, according to the catch, were allowed in addition to the ration.

After the last reduction the party began rapidly to weaken and die. About the 24th of March the whole party was overcome with asphyxia, and nearly lost their lives, owing to the atmosphere being surcharged with carbonic acid. They had lit their alcohol stove in the hut to cook a meal, without previously having removed the rags from the vent-hole in the roof; the remaining oxygen of the air was soon consumed by the stove, and the whole party were seized with faintness, vertigo, and dyspnœa. It was with the greatest difficulty they struggled from their sleeping-bags, and stumbled and were helped into the open air, many fainting away and dropping unconscious after reaching the opening. Being poorly clad for a temperature such as prevailed outside at the time (—46° F.), many were frostbitten. The after-effects of this mishap remained for a long time, and weakened many of them.

After May 12th everything like a regular ration was exhausted, and they struggled on as best they could, catching the shrimps (which they boiled); gathering reindeer moss, which, when boiled, yields a mucilage similar to Iceland moss, and boiling up the sealskin linings of their sleeping bags, from which a gelatinous mass was extracted. It was not till they had exhausted the supply of moss around the camp that they gathered the black lichen (*crêpe de la roche*) growing on the rocks, and boiled it. Dr. Pavy urged strongly against its use, as he had the authority of Kane and Hayes that, when eaten, it would produce a diarrhœa which, in their weakened condition, would be fatal. They had no fuel for artificial warmth, and barely sufficient to allow for melting the ice for procuring drinking water and to cook a meal every other day; so that the living temperature of the hut for the winter was from 5° to 10° F.

They recognized the fact that the nearer they could approach a state of hibernating, the better were their chances of getting through. Only those employed as cooks and hunters exerted themselves much, and they were given a double ration. The rest occupied their sleeping-bags, and slept sixteen to eighteen hours out of the twenty-four. In answer to complaints of hunger, Dr. Pavy's motto was, "Qui dort, dine," which was philosophical without being filling.

There seemed to be but little acute suffering from the lack of food. It was only after the introduction of food into the stomach that the craving became great. For days they went without food without actually suffering. The deaths seemed to take place finally from heart trouble (hydrops pericardii). The feet and face became œdematous; for a day or so they would complain of pains over the heart; have a spasm of pain over the præcordia; a slight general convulsion, and all would be over. Their chief suffering during the winter was from constipation. Many went eight to ten days without a stool, and one as long as sixteen days; the feces became so hardened and impacted in the rectum that at each operation they were obliged to dig the feces out with their fingers, the abdominal muscles being too weak to extrude the mass. Nearly every one would faint after having a stool, from sheer exhaustion.

When it is considered that for nine months they were on the ration as detailed, had nothing but brackish water to drink, no artificial warmth, living in a temperature of 5° to 10° for the winter, with a cubic air-space of 70 feet per man, the condition in which the survivors were found will not be wondered at. There were but seven out of the twenty-five found alive. These were A. W. Greely, First Lieutenant, U. S. A.; Henry Biederlich, Hospital Steward; D. Brainard, Sergeant, U. S. A.; Morris Connell, Private, U. S. A.; Joseph Ellison, Sergeant, U. S. A.; Julius Fredericks, Sergeant, U. S. A.; Francis Long, Sergeant, U. S. A. The first four mentioned were taken on board the flagship "Thetis" and placed under my care, and with them this paper will principally be concerned.

On landing at the camp the condition of the party was so desperate that a delay of two hours was necessary to restore them sufficiently to permit their being removed on stretchers to the boats and taken off to the ships.

Morris Connell, Private, was *in extremis;* was pulseless, unconscious, and unable to swallow; limbs cold and respiration barely noticeable; auscultating over the heart, the sounds were heard very indistinctly. By propping him up, and forcing open the jaws, a teaspoonful of brandy was slowly poured into the back of the throat. The effect of the stimulant was soon noticeable, as a faint pulse appeared at the wrist; in ten minutes he could make an effort to swallow, when more brandy was administered, followed by some warm condensed milk at intervals. The rest of the party were served with brandy, milk, and beef essence, and finally transported to the ships.

The time and space would hardly be allowed me to give more than a brief detail of the cases, and as they closely resemble each other, both in symptoms and treatment, I will confine myself to the case of Lieutenant A. W. Greely more particularly, alluding to anything peculiar in the other cases.

June 22d, 11 P.M., A. W. Greely, Lieutenant, U. S. A., æt. 40. Disease, asthenia. On admission he fainted after being carried below in the ward-room, and vomited; administered ammoniæ spts. aromat. 6 c.c. (100 minims), renewed in ten minutes; placed him in a berth, gave a teaspoonful of raw, fresh beef,

minced; clothes were carefully cut off of him and heavy red flannels, previously warmed, substituted.

On examination his body emitted a sickly, offensive odor (as of stale urine); emaciated to a degree. The skin hanging from his limbs in flaps; face, hands, and scalp blackened with a thick crust of soot and dirt (having not washed or changed his clothing for ten months).

Nervous system: Excitable and irritable, at times almost irrational; eyes wild and staring; insists on talking, craving news, and demanding food; complains of no pain.

Digestive system: Tongue dry and cracked, heavy brownish-black coat; ravenously hungry, abdominal cavity hollow and lying almost in contact with the vertebral column; no movement of bowels for six days; liver dulness, on percussion, confined to right hypochondriac region.

Respiratory system: Respirations 12 per minute; auscultation and percussion reveal no abnormal condition of the lungs; vesicular murmur puerile.

Circulatory system: Pulse 52, soft and compressible; auscultation shows marked murmur (blowing) in systole over base of heart.

Integumentary system: Skin cold and clammy, sickly odor emanating from it, shrivelled and sallow; temperature 97.2° (under tongue).

Locomotor system: Great muscular waste, unable to move or stand without support; body weight, 120 pounds; weight before leaving Fort Conger in August, 1883, 168 pounds.

Urinary system: No specimen obtainable.

Treatment, from 11 P. M. till 8 A. M., alternated every half hour; teaspoonful of raw, fresh beef (minced) with teaspoonful of milk punch; enjoined strict quiet; pulse then rose to 60 per minute, soft; temp. 97°.

23d. Nervous system: Mind still active and restless, compelled to allow him some home letters to read, after which he became more composed; has not closed his eyes; talks rationally, but shows loss of memory, as he often repeats himself.

Digestive system: Had a small, highly offensive stool; felt quite faint afterwards; passed considerable wind from bowels; abdomen tympanitic; tongue still dry and coated.

Circulatory system: Pulse slightly stronger, 60 per minute; respirations 12 per minute.

Integumentary system: Same offensive odor; temp., A. M., 97.8°; P. M. 98°.

Locomotor system: Still unable to raise himself up without help; muscles very soft and flabby; some stiffness and pain in the joints.

Urinary system: Urine passed in 24 hours 1630 c.c. (55 ozs.), sp. gr. 1014, acid, highly albuminous (one-tenth tube).

Treatment: Continue raw fresh beef, at intervals of an hour, with a raw onion finely cut up, added also milk punch, one-half ounce every two hours; no medication.

24th: No sleep; mind more tranquil, but too active; great desire to talk and read; less persistent in demanding food; complains of soreness in limbs; tongue presents a moister appearance; bowels slightly distended with gas, no stool; pulse 62, not so thready; heart sounds stronger; still a pronounced anæmic murmur; blood examined microscopically shows large increase of white corpuscles; at first the field (one-tenth objective) appeared filled with the nucleated corpuscles; close examination showed the proportion to be about one to twenty red; the red corpuscles show but little disposition to cohere and run into "rouleaux," and lacked the distinctive biconcave disk shape; edges full and round (not ragged); urine passed in 24 hours 1660 c.c. (56 ozs.), highly albuminous, no casts revealed by microscope; skin clammy, dirty mottled yellow; temp., A. M., 97.6; P. M. 98°; muscles sore; slight œdema of hands and ankles.

Treatment: Sponging with tepid water, afterwards briskly rubbed with flannels and a little linimentum saponis; four ounces, of oatmeal (thoroughly boiled) allowed in morning; beef essence, Liebig's, ʒj, in hot water every four hours; continue scraped beef and onion; no medication.

25th. Marked improvement; mind more tranquil; talks quietly without excitement; slept two or three hours naturally, awoke refreshed; tongue beginning to clean; had a large, dark, semi-solid stool; odor offensive in the extreme, evidently but little biliary secretion poured into the alimentary canal; pulse 65, some strength; respiration 14, principally costal; skin losing clammy feel, its emanations still sour and offensive; temp., A. M., 98.2°; P. M., 98°; muscles sore; ankles puffed.

Treatment: Shampooing muscles with dry cloths. No change in diet. No medication.

26th. Allowed to sit up in bed and read a little; slept six hours soundly during the night, mind tranquil, has a loss of memory of words; tongue cleaning, still has heavy coat at back; bowels moved twice, stools pitchy and offensive; abdomen tympanitic, considerable borborygmus. Pulse 65; heart sounds stronger, murmur still pronounced. Urine passed in 24 hours 1800 c.c. (61 ozs.), sp. gr. 1016; albumen not decreased; no change in condition of skin. Temp., A.M., 98°; P.M., 98.8°.

Treatment: Sponging and friction. Same dietary with tr. ferri muriat., 5 c.c. (80 minims) ter in die.

27th. Still extremely weak; voice stronger; mind easier; amnesic aphasia marked; appetite still morbid, always hungry, considerable flatulence; no stool; aspect of skin somewhat improved in appearance, still dirty yellow (no petechiæ). Temp., A.M., 98.4°; P.M., 98.8°; pulse 66; respiration 14; urine albuminous (1-12 tube) 1950 c.c. (66 ozs.) in 24 hours, sp. gr. 1018; muscles beginning to fill out, and are very soft.

Treatment: Dietary increased to 8 ounces of broiled steak in morning; continued tr. ferri muriat.

28th. Gaining strength; dressed and sat up for a couple of hours, then felt exhausted and returned to bed; mind quite tranquil; slept well; appetite still morbid; bowels moved, no change in character of stool; liver still inactive. Pulse 66, fairly good tone; anæmic murmur not so marked. Temp., A.M., 98.2°; P.M., 98°; urine passed in 24 hours 1860 c.c., (63 ozs.), sp. gr. 1017, albumen present.

Treatment: Takes food at five stated intervals: 6 A.M., oatmeal, 4 ounces; broiled steak, 8 ounces.

10 A. M., Liebig's beef essence, ʒj, in a teacup of warm water. 2 P. M., one soft boiled egg with milk toast. 6 P. M., raw minced beef and onions. 10 P. M., Liebig's essence of beef. Continue tr. ferri. muriat., 6 c. c. (100 minims) ter in die.

29th.—Dressed and was assisted to walk in ward-room a few steps; muscles soft; very weak; limbs filling out; body-weight 129½ pounds (gain of 9½ pounds for the week). Pulse 68; urine 1650 c. c. (56 ozs.) in twenty-four hours, albumen less; temp., A.M., 98°; P. M., 98.4°, normal; bowels moved naturally, stools still pitchy and offensive.

Treatment: Continue the same.

30th.—Sleeps naturally and awakes refreshed; allowed to read and talk; walks around for an hour or so with support; limbs filling out; feet œdematous toward night; appetite still morbid, unable to be satisfied with his allowance; good movement of bowels; albumen disappearing from urine; heart sounds stronger; temperature normal. Continue restricted diet and iron.

July 1.—Felt quite refreshed on awaking; had slept well during the night; enjoyed morning meal and ate without asking for more. As the sun was shining brightly, was assisted on deck, and sat in the air (well bundled up) for an hour; had but little appetite for midday meal; at 4 P. M., a small, dark, offensive stool; strained considerably, and was much exhausted afterwards (nearly fainted); administered spts. frumenti ℥ss. in water at 6 P. M. Complained of severe pains in abdominal muscles and over the region of the liver (pains resembling hepatic colic); considerable febrile disturbance; pulse 98, temp., 100.2°; administered quiniæ sulph. 30 cgm. (4½ grs.) at 8 P. M.

2d.—Feels much prostrated and weak; muscular pains and soreness over abdomen and back; complexion sallow; appetite poor. Temp., 8 A. M., 98.8°; 12 M., 99°; 4 P. M., 99.2°; exhibited hydrargyri chloridi mit., 30 cgm. (4½ grs.), at 8 A. M. Repeated dose at 2 P. M.: bowels moved three times, last evacuation watery; felt weak, but free from cramps; headache disappeared; light diet of oatmeal and milk; discontinued tr. ferri muriat.

3d.—Still weak; muscular soreness over abdomen; no sharp pains; two loose evacuations from bowels; appetite returning; pulse 68; temp. normal; whiskey toddy ℥ss ter in die.

4th.—Considerable improvement; pains have disappeared from muscles; tongue cleaner; complexion better; allowed to sit up to his meals. Urine much improved, albumen ($\frac{1}{3}$ tube), sp. gr. 1022. Resumed tr. ferri muriat., also vin. Portense ℥j ter in die before meals.

5th.—Gaining strength gradually; muscles soft; knees weak; encouraged to take some exercise daily, weather permitting, in the open air; digestion good; appetite under better control; liver still torpid; regular movement of bowels; skin clearing and has lost its clamminess; sleeps well; continue same treatment. From this time forth there was gradual improvement; blood again examined microscopically—showed marked diminution of white corpuscles. On *8th*, no albumen found in urine. On *12th*, anæmic murmur very indistinct. On *17th*, arrived at St. Johns; condition sufficiently good to warrant his going ashore for exercise; muscles still weak and sore; filled out rapidly.

19th had a slight attack of intestinal indigestion, was living ashore at the Consul's, having committed an error in diet; suffered for two days.

On *25th*, allowed to eat three full meals daily, with certain articles restricted; encouraged to exercise in open air. On the trip from St. Johns to Portsmouth, N. H., (*July 26th to Aug. 1st*), ran into damp, moist weather; felt much prostrated, and muscles ached; given quiniæ sulph. 180 cgm. (27 grs.), every night during the run. On being transferred at Portsmouth, his body-weight was 169 pounds, representing a gain of 49 pounds in six weeks: 9½ pounds the first week, 15 pounds the second week, 8 pounds the third week, 7 pounds the fourth week, 5½ pounds the fifth week, 4 pounds the sixth week.

Remarks.—Vital depression, as exhibited by the temperature is not marked; digestion fairly good all the time; nervous system soon calmed; microscopic examinations of blood exhibited no marked unhealthy character of red blood-globules, but steady decrease of white corpuscles under the influence of the iron; albumen disappearing; anæmic murmur disappearing, showing that it is simply due to hydræmic condition of the blood; liver not secreting; large gain in weight, due to rapid assimilation of food, owing to great muscular waste. Urinary excretion large, 1950 c.c. (66 oz.), in one day, due doubtless to almost total inactivity of the sudorific glands.

U. S. S. THETIS, August 3, 1884.

On relinquishing medical charge of the survivors of the Lady Franklin Bay Expedition, prior to their transfer ashore for treatment, I respectfully submit extracts from the medical journal of this ship, showing their present physical condition and treatment.

1. A. W. Greely, First Lieutenant U. S. A., æt. 40 years. *Present condition:* Able to walk some distance without getting tired; muscles beginning to harden and tone; face still has a swollen appearance, and puffed; complexion sallow. *Digestive system:* Tongue clean and moist; appetite not abnormally large; bowels move regularly; stools large and dark colored, less offensive; passes less wind from bowels; no tympanites; at times heavy feeling over right hypochondriac region. *Circulatory system:* Pulse 78–82; good tone; auscultation over the heart shows almost total disappearance of anæmic murmur. *Respiratory system:* Lungs free from trouble; has slight dyspnœa on exercising. *Integumentary system:* Skin sallow; temperature of body 98.6°. *Urinary system:* Urine passed in twenty-four hours, fifty-six ounces; pale amber; acid; 1024 sp. gr.; no albumen. *Nervous system:* Mind tranquil; memory much improved; slight amnesic aphasia; sleeps well. *Locomotor system:* Muscles soft; has weakness, particularly in the broad muscles of the back (latissimi and trapezii); complains at times of cramps in the muscles of legs. *General condition:* Liver is torpid; muscular system lacks tone; is free from organic disease. *Treatment:* Rest; moderate exercise; dietetic; port wine before meals; pil. quiniæ

sulph. grs. iij at night; pil. ferri et strychniæ citrat. grs. iss after meals.

2. Morris Connell, Private U. S. A., æt. 32 years. *Present condition:* Sallow; muscles weak. *Digestive system:* Tongue clean, furred at the back; appetite abnormally large; bowels free, large stool daily; troubled at times with gaseous dyspepsia; bowels flatulent and tympanitic; liver contracted slightly. *Circulatory system:* Pains over præcordia disappeared; heart sounds normal; pulse regular, 74, lacks strength. *Respiratory system:* Normal. *Integumentary system:* Slightly œdematous about the feet; sallow; temperature of body normal. *Urinary system:* Normal. *Nervous system:* Sleeps well; mind active and retentive; no pains in body. *Locomotor system:* Muscles getting tone gradually. *General condition:* In fair health; free from organic disease. *Treatment:* Dietetic; tr. ferri muriat. ♏xv ter in die; exercise.

3. Henry Biederlich, Hospital Steward, æt. 28 years. *Present condition:* Suffering from chronic rheumatic arthritis in middle joint of ring-finger of left hand; has also at times flashes of rheumatism in joints and muscles. *Digestive system:* In good condition; suffers at times from gaseous dyspepsia; bowels regular; appetite not morbid. *Circulatory system:* Has anæmic murmur over the base of the heart; pulse dicrotic at times, 74 per minute. *Respiratory system:* Normal. *Integumentary system:* Face puffed, ankles œdematous, skin clear, temperature normal. *Urinary system:* Normal. *Nervous system:* Mind clear; has neuralgic pains at times in muscles of chest; sleeps well. *Locomotor system:* Muscles getting stronger and harder; joints at times stiff from rheumatism; middle joint of ring-finger on left hand chronically swollen. Is in fair physical condition and free from organic disease. *Treatment:* Quinine, small doses of potass. iodid., exercise.

4. D. Brainard, Sergt. U. S. A., æt. 28 years. Is in fair physical condition, performs all functions naturally; pulse good, temperature normal, urine normal, feet slightly œdematous, muscles in fairly firm condition. Free from all organic disease. *Treatment:* Dietetic, quinine, tr. ferri muriati, port wine.

5. Julius R. Fredericks, Sergt. U. S. A. In good physical condition; all functions naturally performed; pulse good, temperature normal. Has been under treatment of P. A. Surgeon Ames, on the "Bear."

6. Francis Long, Sergt. U. S. A. In good physical condition. Under treatment of P. A. Surgeon Ames, of the "Bear."

Very respectfully,

EDWARD H. GREEN,
P. A Surgeon.

MEDICAL PROGRESS.

PERMANENT ANTISEPTIC DRESSING.—PROFESSOR ESMARCH, of Kiel, read a paper, at the Copenhagen Congress, on permanent antiseptic dressing.

The healing of all wounds *by first intention*, without suppuration, he said, is the most desirable issue. 2. This method of healing is most certainly obtained by the absolute preventions against infecting material, and by the complete rest of the wounded part. 3. Since every renewal of the dressings disturbs the wounded parts, and renews the danger of infection, a permanent dressing, one which can be left on the part until the wound is completely healed, is that which most nearly conforms to this end. 4. If the surgeon would avoid renewal of the dressing during the process of cure, the wound must be placed under such circumstances, must be so closed and dressed, that neither suppurative irritants nor foreign bodies shall remain in it, and that no blood or secretion from the wound can be retained. 5. The chief conditions for this result are: (*a*) Exact hæmostasis; (*b*) The avoidance of all spaces in the wound; (*c*) Free exit of all secretions; (*d*) The most careful antisepsis, and best antiseptics; (*e*) The use of compressible dressing-materials, which will absorb all the fluids; (*f*) Immobilization of the wounded part.

CONTRIBUTION TO THE SURGERY OF THE INTESTINE.—PROFESSOR MIKULICZ also read a contribution to the surgery of the intestine.

He has in two cases resected, with good results, an invaginated and prolapsed large intestine (in one case to the extent of twenty-eight inches, in the other twelve inches), using a typical intestinal suture (a double row of sutures, one of Lembert's suture, and a running suture for the mucous membrane). This operation is indicated in invagination and prolapse: 1. When reposition of the prolapsed intestine is impossible on account of the swelling; 2. When the prolapsed intestine is partly or entirely gangrenous.

As to the therapeutics of perforation of the intestine, in every case in which perforation of the intestine can be diagnosticated with some probability, laparotomy should be performed, the perforated portion sought out, and the opening closed by sutures, after freshening the edges of the wound. The operation is not contra-indicated by existing peritonitis, if the patient is not already in a state of collapse or sepsis. Mikulicz has successfully performed laparotomy in a case of this kind when there was purulent peritonitis from extravasation of the intestinal contents. This case was most probably one of perforation of a typhoid ulcer.

CONGENITAL SARCOMA OF KIDNEY, WITH OBLIQUE MUSCULAR FIBRES.—BROSIN reports (*Archiv f. path. Anat. und Physiol.*, Bd. xcvi. Hft. 3) a case—the seventh on record—of a child three years of age, who gradually became emaciated during the last two years of life, and had a large swelling of the abdomen, which became hard in the last year. No medical examination was made during life.

At the autopsy, a large hard tumor was found involving the left kidney. Microscopical examination showed it to be of sarcomatous structure; but wherever the connective tissue of the stroma was formed of fibrilli, with few nuclei, transverse muscular fibres were found. These often formed larger groups, and crossed one another in every direction. Of the cases of this kind hitherto reported, the youngest was seven, the oldest thirty-nine months.—*Centralbl. f. klin. Med.*, Aug. 2, 1884.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, SEPTEMBER 6, 1884.

THE GREELY ARCTIC EXPEDITION.

THE Arctic tragedy with its accumulated woes, by which the civilized world has been at once fascinated and horrified, offers to the medical profession some important hygienic and physiological problems. It is, therefore, satisfactory to us to be able to lay before our readers the medical history, for this throws a clear light on the physical and, secondarily, on the mental state of the human wrecks rescued on the very border of eternity. Such a record of incredible suffering and hardships is not unknown in the annals of ocean explorations; but we do not find anywhere a scientific and exact statement of observed results such as that with which we are favored by Dr. Green.

The results of this expedition differ in one important point from former ones: but a single case of scorbutus occurred. The advance in our knowledge of the purpose subserved by the various kinds of aliment, permits the construction of dietaries adapted to the various exigencies of life. Given a route of the proposed exploration, the isotheral and isochimenal temperatures, and the kind and quantity of work to be done, a diet-table can be formed which will be exactly adapted to the conditions present, so that the body will be maintained at its maximum of efficiency. That the aliment furnished to the Greely expedition served its purpose, is shown in the fact that the party was in good condition when it reached its permanent quarters. The solitary case of scurvy would not have occurred, probably, if the other circumstances had been propitious in the affected individual.

Another lesson is the very small amount of food which may suffice to keep the human machine in a state of efficiency. Compared with some other historical examples, the food supply allowed each member of the party at Cape Sabine was liberal. It was in the aggregate nearly fifteen ounces. At the siege of Paris, the daily ration was at one time reduced to ten ounces of bread and one ounce of meat, or eleven ounces in all. The ration allowed the United State soldiers in the Andersonville prison, was five ounces of bacon and twenty ounces of unbolted corn-meal, which was not equal, in point of material available for nutrition, to that given the Greely party.

In view of the small amount of aliment allowed at the outset, and subsequently greatly lessened, an attempt was made to assimilate their lives to that of hibernating animals. This, we believe, was unwise. Although the amount of food and the low temperature precluded active exercise, they would have done better to accommodate themselves, as nearly as possible, to the conditions of health in normal surroundings. A hibernating animal has a store of fat laid up for consumption during the period of repose. The accumulating carbonic acid lessens the activity of the nervous centres, and induces a comatose state during which all the functions are inactive. Such a state of things is impossible to man, and the attempt to accommodate themselves to such abnormal conditions only produced a pathological state and accelerated waste. The air-space allowed them was entirely inadequate, and the enforced lack of attention to personal cleanliness prevented excretion by the skin. Hence animal heat was not properly developed, and the food taken was not efficiently utilized, either to promote nutrition or to maintain the body temperature. Suitably placed as to their hygienic surroundings, and the functions sufficiently exercised, the amount of food allowed at Cape Sabine, at the beginning of their stay there, might have been much lessened, and yet have proved sufficient.

In the process of slow starvation two beneficent results greatly lessen the terrors of the situation. At a certain point, the desire for food ceases, until the stomach is roused from its functional torpor by the introduction of some aliment. In those cases of voluntary fasting with the details of which the public is now and then regaled, it is probable that the experimenter experiences but little the pangs of unsatisfied appetite after the first few days of torture. Such was the experience of the Greely party.

The other beneficent experience of the starving, is the pleasing delirium in which feasting on sumptuous viands is indulged—in such a mode does Nature offer compensation in this dire extremity. But the delirium may take other forms. In the struggle for existence, when only the animal instinct remains, and men living in the state of animals lose the distinctive qualities of the civilized state, it is not surprising that mere savage feelings sway them entirely,

and hence the delirium, if not occupied with the pleasing illusions of feasting, may take the form of an aggressive animality.

THE CHOLERA CONFERENCE AT BERLIN.

IN the last two issues of THE NEWS we laid before our readers an extended abstract of the address of DR. KOCH at the recent conference held at Berlin for the discussion of the cholera question. The subsequent discussion was participated in by Virchow, Leyden, Hirsch, Fränkel, Schubert, Bardeleben, and others.

The important conclusions to be drawn from Koch's paper may be summarized as follows:

1. Cholera is the direct result of the lodgement and proliferation in the intestinal walls of a distinct bacterium, usually comma (,) shaped, but frequently, also, semicircular or s shaped, suggesting the apposition of two bacteria. It may also grow out into a spiral thread resembling the spirochæta of relapsing fever, whence Koch doubts whether it should be ranked as a bacillus, as a transition-form between a bacillus and spirillum, or a true spirillum.

2. The comma-bacillus is easiest found in the earlier stages of the disease, being later obscured by numerous other forms of bacteria. It is distinctive of the mildest as well as the severest cases, and has, therefore, an important diagnostic value.

3. It is capable of successful culture in broth, milk, on potato, and especially in gelatine, in which it grows peculiarly, producing a gradually extending liquefaction of the gelatine around the growing colony.

4. Thriving best at a temperature of 68° to 136° F., it is not destroyed by a temperature of 14° F.

5. It is, however, readily killed by drying, and it does not, therefore, pass into a state of latent activity or resting state, as does the bacillus of anthrax and vaccinia. The removal of the nutrient medium for 24 hours or even less, and an acid reaction, also destroy the bacillus.

6. Under ordinary circumstances the bacilli, introduced by the mouth, are destroyed in the stomach, but given a derangement of this organ due to errors of diet or other cause, and the bacillus is enabled to escape the action of the acid gastric juice and to reach the alkaline intestinal fluid, where it proliferates, sets up irritation, diarrhœa, and all the typical symptoms of the choleraic seizure.

7. Cholera can only spread by human intercourse, and cannot have an autochthonous origin, all observation going to show that the delta of the Ganges is its invariable source.

8. The harmful effect of the bacillus is probably not through its irritant action alone, because this is too limited in extent, but rather also through a poison or ptomaine which it generates, such as is produced by bacteria in putrefaction.

We have followed carefully the methods and reasoning of Koch, and have been favorably impressed by both. There is to us, too, a stamp of authority about these observations which cannot be admitted of those on tuberculosis. It cannot fail to be noted, however, that the whole subject is one of greater simplicity, and therefore easier of solution, than the tubercle question. At the same time we deem it premature to accept unqualifiedly the first and most important of his conclusions, because we believe that in a science like our own, where mathematical demonstration is impossible, we dare not, on the testimony of a single individual, however careful and accurate he may be, accept a conclusion until it is verified by others. The results of further observation must therefore be anxiously awaited.

The only observers who have as yet had the same opportunity as Koch are the French Commissioners, Roux and Strauss, who, while they admit the finding, among a large number of microörganisms, of one resembling the comma-bacillus, they do not attach much importance to it. They also call attention to the finding of a comma-shaped bacillus by Maddox, of London, in a reservoir of water, by Malassez in dysenteric stools, and by themselves in the vaginal mucus of a woman with leucorrhœa, and in the mucous uterine secretion of a woman who had commencing epithelioma of the cervix.

Koch himself admits that all efforts to produce the disease in the lower animals by inoculation of the bacillus have been unsuccessful, but argues against the conclusiveness of this fact as an objection, that cholera does not occur in any of the lower animals. It is true that pigs fed upon the choleraic material died of convulsions in from fifteen minutes to two and a half hours; but Koch says this must have been an "intoxication" rather than an infection, because another pig fed upon the intestinal contents of one of those thus killed was not affected. It will be remembered that it has, heretofore, been believed that certain lower animals are subject to cholera. Further investigations are evidently required in connection with this point.

The discussion which followed the address was limited in some directions by the fact that few present had had practical opportunities of the kind enjoyed by Koch, but was facilitated by the presentation of sixteen questions, of which we can now only dwell upon two or three of the more important. First of these is, of course, the question: "Is the infective material of cholera identical with the comma-bacillus?" To this Virchow answers "not proven," seizing at once the weakest point of Koch's position —that cholera has not been communicated through

its inoculation. At the same time, he admits that this is not an absolute refutation, and says further that if any one of the numerous organisms found in the dejecta of cholera be its cause, the probabilities are decidedly in favor of the comma-bacillus. The entire history of cholera, including its distribution, would seem to demand that a living organism is responsible, and the fact that Koch found that in certain cases the dejecta and the intestinal contents of cholera patients were made up almost wholly of cultures of this bacillus, that on the soiled linen—acknowledged to be the most dangerous means of communication—the growth of the organism is most active, leave it scarcely possible to conclude otherwise than that the bacillus is the essential cause. On the whole, then, we may say that Virchow inclines to accept the proposition.

Hirsch called attention to the fact that cholera morbus so often simulates in all respects Asiatic cholera, and furnishes some reasons for regarding it of an infectious nature. Koch says, in reply, that recent opportunities to investigate the morbid anatomy of this affection have failed to discover anything analogous to the comma-bacillus. Nor has he found it elsewhere, although here we must admit the force of Virchow's objections that many test-observations must be made before this can be admitted.

Another point of interest brought out in the discussion bearing on the diagnostic value of the bacillus was the practicability of its detection by any except those favored by the possession of laboratory facilities. The conclusion arrived at and shared in by Koch was that the difficulties are not so great, but that the educated physician anywhere may be qualified to detect it, particularly with the aid of cultures, which are especially distinctive in the case of this bacillus.

In the discussion as to the existence of a period of latent activity of the bacillus, came up the question of the origin of isolated cases of cholera, apparently communicated by the clothing carried in a trunk from a distant source of infection. In the same category must be placed the cases named by our esteemed contributor, Dr. Henry Hartshorne, in his letter in our issue of the 30th ult. Koch met the former objection by showing that the interval was within that of the viability of the comma-bacillus under circumstances favorable to its vitality—that is, moisture. Cases of the kind related by Dr. Hartshorne are always apocryphal, and can never be admitted in determining a scientific question.

Whatever may be the fate of the comma-bacillus, the address and the discussion must be regarded as most important and memorable. The series of questions were calculated to exhaust the subject thoroughly, while the professional eminence of the debaters insured and resulted in a cross-examination of the distinguished mycologist, in which he acquitted himself as creditably as in the original discourse.

MR. TAIT'S ADDRESS.

The address on Abdominal Surgery made before the Canada Medical Association on August 25th, by Mr. Lawson Tait, is given in full in this issue of The News. Its distinguished author manifests in it great ability, independence, and fearlessness—indeed some parts seem like a bold challenge to more than one person of acknowledged power and fame.

Let us first recognize the tribute Mr. Tait pays to the professional knowledge and skill of America in the prediction that soon students will come to the medical schools of this country rather than those of Europe, and seriously ask those who find nothing good in our system of medical education, whether this judgment of an eminent foreigner ought not to suggest to them the possibility of error in their constant disparagement of medical affairs here, and eulogy of foreign professional education.

Mr. Tait gives scant praise to Dr. Ephraim MacDowell, the great pioneer in ovariotomy; telling us that he, in 1809, imitated Robert Houston, of Glasgow, who, in 1701, made a "successful ovariotomy." It seems rather late in the day to adduce Houston's case as an ovariotomy, for this operation was simply a free incision into an ovarian tumor, evisceration of its contents, and "removal of several pieces of membrane." Such an operation done now would be called a partial or uncompleted ovariotomy, and the resemblance between an accidental, partial ovariotomy, and an intentional, complete ovariotomy is not so obvious that the great Kentucky surgeon should be spoken of as imitating the Glasgow operator, of whom, most probably, he had never heard. Mr. Tait's native land, Scotland, has enough professional glory without his taking a leaf from the laurel crown of MacDowell, and giving it to one who has no right to it, as the profession generally has judged.

Just praise is given Mr. Baker Brown, who certainly was one of the best operators London ever had. Mr. Tait clearly upholds strict cleanliness in abdominal surgery, in contrast with antiseptic practice, and decidedly to the advantage of the former. But this is a question that cannot be settled by the experience of one, or of half a dozen operators.

Omitting reference to the many hard blows given the most famous of English ovariotomists, some of which may seem to the casual reader as expressing needless criticism, probably the most interesting as well as the most valuable part of the address is that relating to the removal of the uterine appendages for uterine myoma, or for chronic and incurable disease of the ovaries or oviducts; this operation in the latter case is peculiarly Mr. Tait's, not only as to his being the first to perform it, but also as to the fre-

quency with which he has done it, and to his having had as yet comparatively few followers. The profession will be very glad to have from Mr. Tait so clear and condensed an exposition, as he has here given, of the conditions he regards as requiring his operation, and the results following it.

Battey's operation he eyes somewhat askance; but he has not given it full consideration; he has not weighed all the indications for it that Battey himself has presented, and therefore his judgment is only qualified and partial, not complete and conclusive.

It is to be hoped that in some of the great cities of the United States which Mr. Tait will visit before his return to England, he may be induced to give to the profession more at length his views upon abdominal surgery, especially concerning the operation with which his own name is connected.

CIRSOID TUMORS OF THE HAND.

IN a paper read before the Société de Chirurgie, and published in the *Union Médicale*, No. 65, 1884, POLAILLON, as the result of the study of 26 cases, including one of his own, arrives at the conclusion that the only efficient treatment of cirsoid aneurism of the hand consists in obliteration or destruction of the vessels of the tumor itself. Compression was futile in the 7 instances in which it was resorted to; and only 2 of the 13 cases in which the arteries of the forearm or arm were ligated were successful.

When the tumor is small, circumscribed, and non-adherent to the deep tissues, excision is indicated, and in certain cases the vessels may be destroyed by the thermo-cautery or chloride of zinc; but as a general measure, by far the surest and safest procedure, according to Polaillon, is the injection of a dilute solution of perchloride of iron, conducted under proper precautions. The circulation of the tumor having been arrested for ten minutes by compressing the brachial artery or the ulnar and radial arteries, a tubular needle is made to penetrate the vessels themselves, and not the connective tissue which surrounds them, as will be indicated by the escape of arterial blood, when the canula of the charged Pravaz syringe is passed through the needle, and from five to ten drops of the solution deposited in the vessel. One injection rarely suffices, but the operation is so free from danger that it may be repeated at intervals of five or six days until the tumor becomes hard, and its pulsation and souffle cease.

That this plan of treatment is not always successful is shown by Polaillon's own case, in which, ten years after an apparent cure, the symptoms were found to have recurred, and the tumor had increased in size. Had the author been thoroughly conversant with the literature of the subject, he would have had to add that injection is not always safe, as Spence has recorded a case in which it had to be followed by amputation; and Keen has, moreover, reported an amputation after injecting a traumatic aneurism of the hand with subsulphate of iron.

While it is true that hæmorrhage may be excessive when the tumor is excised without taking the precaution to apply the bandage of Esmarch, it is none the less true the bleeding may be averted by resorting to that preventive measure, and that every case of excision as yet reported has been successful. As compared with the injection of perchloride of iron, we have no hesitation in declaring that excision, cautiously and skilfully practised, is the more rapid, safe, and efficient means of dealing with arterial varix, and in making this statement, we believe that we express the views entertained by the most experienced surgeons on this side of the Atlantic.

IN the thirty-six hitherto recorded examples of ligation of both common carotid arteries, either simultaneously or at variable intervals, there is not a single one in which the operation was demanded for spontaneous aneurism of both trunks. Hence, the case reported by RIEGNER, of Breslau, in the *Centralblatt für Chirurgie*, No. 26, 1884, in which this condition existed, is to be regarded as a surgical curiosity.

On the 21st of September, 1881, Riegner successfully tied the left common carotid of a man fifty-four years old, for a spontaneous aneurism of that vessel. On the 5th of April, 1884, the right artery was ligated for a similar affection of its trunk, the tumor having made its appearance a year and a half after the first operation. On the following day there were slight delirium and motor paralysis of the left arm, but these symptoms disappeared in twenty-four hours, and the patient was discharged on the eighteenth day.

THE Navy Department has promptly acted upon our recommendation of last week, and has instructed the Court of Inquiry to ascertain whether color-blindness on the part of any of the officers or men of the Tallapoosa was responsible for the collision at sea, by which that vessel was lost.

Fortunately, as the Board is sitting in Boston, it will be easy for it to obtain the requisite expert aid to conduct satisfactorily the investigation on this point, and without which it would be difficult for it to reach a correct conclusion. Tests with lanterns and flags, which naturally suggest themselves to the lay mind, have been found to be fallacious, since, under favorable circumstances, a color-blind person may make correct guesses at the colors by means of the difference in the intensity of light in which they appear to him. And in using Holmgren's worsted test, which is the only reliable test to obtain correct results, the worsteds must be properly chosen, and the examiner thoroughly understand the method.

SOCIETY PROCEEDINGS.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Eighth Annual Meeting, held at Highland Falls, N. Y., August 27, 28, and 29, 1884.

(Specially reported for THE MEDICAL NEWS.)

THE Eighth Annual Meeting of the American Dermatological Association was opened at Highland Falls, on the 27th of August.

After the report of the Council and the transaction of the routine business of the Association, the PRESIDENT, DR. R. W. TAYLOR, of New York, delivered a brief introductory address, and then declared the meeting open for scientific work.

DR. W. A. HARDAWAY, of St. Louis, reported

A CASE OF MULTIPLE XANTHOMA OF THE SKIN, EXHIBITING THE PLANE, TUBERCULAR, AND TUBEROUS VARIETIES OF THE DISEASE.

In summing up the history of the case, the author called especial attention to the following points: that the bronzing of the skin preceded the development of the xanthoma by a number of years; that the eruption was perfectly symmetrical, with the exception of the lesions on the side; the involvement of the mucous membranes, and the undoubted implication of internal organs; the distribution of the tubercles on the side, which would seem to show that the nervous system exerted an influence in the development of xanthomatous lesions; the presence of such lesions in tendons and in the areolar tissue; and the probable implication of bone-structure in the same process; the evidence, although slight, of sugar in the urine; and, finally, the fact that some of the growths had disappeared.

From a study of this and other cases, and of the literature of the subject, he ventured to suggest that xanthoma was a diathetic affection, and that the connection of the disease with hepatic derangement was entirely secondary, or, in other words, that the jaundice occurred in consequence of the deposition of xanthomatous tubercles in the liver. He believed, however, that the liver was peculiarly prone to become the seat of these growths. It seemed to him, also, probable that in persons having what, for want of a better term, he would call "the xanthomatous diathesis," certain conditions of irritation or of unusual motion might provoke a local deposit *in situ—e. g.*, on the lids, over joints, etc. It seemed possible that his patient might owe his zosteriform deposits to an abortive attack of herpes zoster.

DR. S. SHERWELL, of Brooklyn, alluded to the old view that the liver was usually primarily affected in this disease, an opinion which he had never been able to corroborate in a large number of cases which had come under his observation. He thought that in the case reported, the affection of the liver and the consequent icterus were wholly secondary. In his own cases the patients were all in otherwise good health. One case in particular, which showed more than five hundred lesions, discrete and confluent, was that of a man in robust health with an admirable hereditary history, and with not the slightest evidence of hepatic derangement.

DR. J. C. WHITE, of Boston, said that he believed it extremely rare to find jaundice associated with xanthoma he himself having encountered it in only one instance of the many that he had seen of the disease, and he had paid especial attention to the point during the past twenty years. This remark he would apply to xanthoma of all grades of severity. He had seen only one case of xanthoma multiplex. He had often noticed a deposit of permanent pigment in both upper and lower eyelids, which rendered the contrast between the two colors very striking. He had never been able to trace any connection between xanthoma and a diathesis, but he had seen several cases of the disease in the same family. In listening to the reading of the paper he had been surprised at the statement that sugar had been found in the urine, in view of the low specific gravity of that fluid.

DR. L. A. DUHRING, of Philadelphia, remarked that a point of great interest in the case was the presence of the intense pruritus, beginning with the jaundice, and not with the disease. He had been much interested in tracing a possible relationship between the tumors formed in this disease and growths usually held to be of a different character, met with in the disease known as urticaria pigmentosa. He believed that two classes of affections had been described under this title, viz.: cases of true urticaria, with lesions of unusual persistency, and cases partaking more of the nature of xanthoma, with intense pruritus and pigmentation, and the formation of distinct papules and tubercles with the characteristics of urticaria. Such cases he regarded as identical with those which Tilbury Fox had described and figured in his Atlas under the name of "Xanthelasmoidea." Intense itching was also a feature of that disease. He had no doubt that a disease existed having a close relationship to xanthoma multiplex, but differing from it in that the lesions undergo involution, and run a definite course. He alluded to the fact that English observers, Dr. Morris in particular, claimed to have noticed spontaneous disappearance of xanthoma multiplex.

THE PRESIDENT, DR. R. W. TAYLOR, had also been unable to associate xanthoma with a particular diathesis, he having seen the disease in the strong as well as in the dyspeptic, the gouty, or the jaundiced. He had seen only one case of general xanthoma, which was in a woman in whom the entire body, as well as the face, was involved. If involution of the lesions ever did occur, he believed that it would take place on the body, for he thought that all would agree that it never did on the face. He recalled one case in which involution did take place, and in which it was attended with atrophy of the skin.

DR. HARDAWAY, in closing the discussion, stated that he had only the patient's statement in proof that involution of some of the lesions had taken place, and had not observed it himself. He had been very much interested in the osseous lesions which the case presented, which were involved in great obscurity. In the literature of the subject he had found only one allusion to such lesions, by Colcott Fox, who spoke of peculiar changes in the bones of one case, "due to the rheumatic or gouty state."

Evening Session.

Dr. J. Nevins Hyde, of Chicago, read a paper entitled

A CLINICAL STUDY OF LUPUS ERYTHEMATOSUS OF THE HAND.

He described, in detail, the symptoms of the disease as exhibited by four patients under his observation. In each the discoid variety of the disease was displayed upon one hand, and of the four patients one only had facial lesions, the latter appearing years after full evolution of lupus erythematosus had occurred upon the right hand. In several of the cases the fingers were involved, and in one the palm was chiefly invaded.

From a study of the similar cases recorded in dermatological literature it appeared that the average age of the patients was somewhat over twenty years, nearly two-thirds of them being women, confirming thus the observation made by Kaposi, in 1882. The cases in which the hand or hands were involved were all reported by either English or American observers.

Dr. J. C. White stated that he had seen three or four cases of lupus erythematosus in which the hands alone were affected. He had seen other cases of disseminated lupus erythematosus in which although the lesions were widely scattered the hands were free. In all these cases he had been unable to recognize any general disturbances which would indicate a depraved condition of the system. He believed that cases of the disease in which the hands were involved were not so very rare, but that the affection was often mistaken for other things.

Dr. Sherwell had never seen the disease on the palms, but had seen it on the backs of the hands.

Dr. Taylor had seen two cases of this variety. They were well nourished, and seemed free from any diathetic taint.

Dr. Hyde stated that his main object in writing the paper was to point out the ease with which the affection could be recognized, and to enrich the scanty literature of the subject.

Dr. S. Sherwell then offered

A SUGGESTION RESPECTING THE TREATMENT OF ACNE AND ACNE ROSACEA IN THE MALE SUBJECT.

He stated that while in the text-books on dermatology much stress was laid on disturbances of the gastro-intestinal tract as reflex causes of the diseases in question, but little attention was usually given to disorders of the genital apparatus in the male. In America only two authors had recognized the importance of such disorders, viz., Piffard and Hyde. He fully coincided with them in this respect, and after speaking of the benefits which he had obtained from the use of ergot in these diseases occurring in the female, he proceeded to call attention to the use of the cold steel sound in the male. He believed that in some of these cases there was a condition of chronic passive hyperæmia of the urethra, especially at the junction of the bulbous and prostatic portions, in relieving which the use of the cold sound was often of great benefit. He detailed a case in a young man, and alluded to another which closely resembled it, in which he had, at various periods, treated the disease (acne rosacea) with local agents as well as measures directed to the improvement of the general health, with but temporary benefit. Finally, he had resorted to the gentle introduction of a cold sound at intervals of, at first, three days, and later, of a week. Improvement in the condition of the face began almost immediately, and now the patient was almost well. During this period no change had been made in the treatment in other respects.

Dr. A. R. Robinson, of New York, supposed that all would agree that the cause of acne was usually some disturbance which acted in a reflex manner, except in strumous cases, in which, of course, cod-liver oil would render great service. Of course, if urethral irritation were present, the use of sounds might do good, and he thought the suggestion an eminently philosophical one.

Dr. G. H. Fox, of New York, called attention to the fact that patients, after putting themselves under a physician's care, often made great changes in their hygienic regimen, with or without instructions, and he thought that, in many cases, this might be the true cause of an improvement which the physician might attribute to some special plan of treatment. The suggestion concerning the use of the sound impressed him favorably. He had seen eczema of the anus and scrotum relieved by the passage of sounds.

Dr. Sherwell was positive that there had been no change in the regimen of the two cases which he had described, and the symptoms of intense irritability of the urethra at the point mentioned had been rapidly subdued by the use of the instruments.

Dr. James C. White then reported

A CASE OF UNILATERAL CHROMIDROSIS,

in a workman in a sugar-refinery, whose shirt had been stained of a bright-yellow color for a period of several months. After wearing the garment for a few days, the left side, from the shoulder to the flap, looked as if stained by saffron. There was apparently no excessive perspiration of this side of the body, nor were the patient's garments stained at all elsewhere. An analysis of the material absorbed by the shirt showed that it was of an oily character, readily extracted by ether, and yielding peculiar absorption-bands by the spectroscope. Its nature was not more definitely determined. Its source—*i. e.*, whether excreted by the sweat-glands or sebaceous glands—was also uncertain. The color was not due to the presence of bacteria, which have been found in some of the few cases of yellow sweat on record. The affection was immediately controlled by local treatment, and had not recurred after an interval of four months' observation.

Dr. White also reported some

CASES OF DERMATITIS SUPPOSED TO HAVE BEEN CAUSED BY CONTACT WITH ARSENIC.

He gave brief notes of three cases of *arsenical dermatitis* in connection with the report of a train of uncommon cutaneous manifestations in a mother and her new-born infant, after confinement within a chamber the walls of which were covered with arsenical pigments. The object of the paper was to raise the question, How far is the apparent case of "pityriasis maculata et circinata" in the mother dependent upon the presence of arsenical compounds in the atmosphere of the lying-in chamber, an affection concerning the etiological relations of which nothing is known? In

the infant, the symptoms were of an eczematous type, with unusual manifestations of intertrigo.

DR. SHERWELL said that the paper recalled to him an obscure case of bullous eruption now under his care (which he had called pemphigoid). The bullæ were large and very tense, sprang up rapidly and on all parts of the body of the patients—a man and his wife.

DR. WHITE asked if they had recently landed, and, on being answered in the affirmative, said that they were probably cases of mosquito-poisoning. He had seen cases of bullous eruptions in persons who had never before been exposed to the attacks of these insects, in which the lesions were often as large as pigeons' eggs. He alluded to a case of the kind in which lesions appeared during the winter, when no mosquitoes were about. On visiting the home of the patients he found that they lived in a damp, cave-like place, in which he found numerous large and active mosquitoes. He thought the presence of the bullæ on the body and thighs in such cases could be explained by the throwing off the covering of the bed during sleep. He felt certain that if Dr. Sherwell would investigate he would find that his cases were of this nature.

(To be concluded.)

CORRESPONDENCE.

THE EIGHTH INTERNATIONAL MEDICAL CONGRESS.

(From our Own Correspondent.)

COPENHAGEN, August 17, 1884.

THE Eighth International Medical Congress is among the things that were. Its promoters and managers have good reason to be proud of the results they have obtained, the number and character of the papers presented, the interest manifested in the work of the Sections, and the magnitude and splendor of the social entertainments provided. When it is remembered that the total population of the kingdom of Denmark is only half that of London, one can hardly express too great admiration for and astonishment at the hospitality with which Copenhagen has received her guests.

The total number registered as members of the Congress was seventeen hundred and forty, and the number of foreigners present was greater than at any previous Congress, even that at London not excepted. Of the Danish members many were not physicians. No credentials were required; apparently any one could register, and obtain a ticket of membership, on paying the fee, which for foreigners was twenty kroners (about $5.60), and for Danes fifty kroners (about $14.00).

The opening of the Congress in the hall of the Palace of Industry, on Sunday, August 10, was an impressive scene, although not so imposing as the opening scene of the London Congress in St. James Hall, owing to the fact that the room was much smaller, and there was no platform upon which to gather the notabilities in full view of the audience. The ceremony was very simple, consisting of an address of welcome by the President, Prof. Panum, and short congratulatory addresses by Paget, Pasteur, and Virchow, after which the President again mounted the rostrum, and gave a history of the organization of previous Congresses. The King and Queen of Denmark, and the King of Greece, with many Court officials, were present, but their part in the ceremony was entirely a passive one.

On the evening of Sunday, the President gave a dinner at the Hotel d'Angleterre to the notabilities of the Congress, about two hundred guests being present. According to the Danish custom, speaking began after the first course, and continued at intervals throughout the dinner. On this, as on most other occasions of a like character during the Congress, no American was requested to speak, it being apparently considered that Sir James Paget should always represent all the English-speaking members of the Congress. Certainly, no more eloquent orator could have been found; but the American representatives were nevertheless somewhat surprised and annoyed at the complete omission to recognize the United States as a separate nation.

The arrangements for registration were good. All who had, prior to August 1, notified the authorities of the Congress of their intention to be present, found their cards of membership duly prepared and ready for them on their arrival.

On Monday morning, the work of the Sections commenced, and went on for the most part smoothly and according to programme. The absence of Mr. Lister, who was to have presented the first paper in the Surgical Section, created some confusion in the arrangements of that Section; but there was abundance of material to fill the gap.

Monday evening was devoted to entertainments by the various Sections of the specialists connected with each department. This proved to be an excellent arrangement as a means of bringing together socially those who are interested in the same subjects, and is an example which might well be followed in future meetings of this kind.

The address of Pasteur in the general session, on Monday afternoon, was merely a repetition of what he has already published with regard to hydrophobia, with the addition of the report of the Commission appointed by the Minister of Public Instruction in France to verify his statements. Pasteur looks very well, but moves slowly and with some difficulty, not having complete control over the muscles of one side.

On Wednesday, the Congress took a recess to permit of an expedition to Elsinore and the Castle of Kronborg, celebrated as the scene in which is laid the play of Hamlet. A very elegant lunch was provided in the Castle by the Reception Committee, and, after the lunch, the company went out on the grassy ramparts overlooking the sea, and were served with coffee. The day was pleasant, and the whole scene was exceedingly picturesque.

On Thursday evening, the city of Copenhagen gave a dinner to the Congress in a temporary building erected for the purpose at the water's edge. Twelve hundred persons were seated at this dinner, which was elaborate and exceedingly well served. During its progress, steamers gaily decorated with flags were constantly passing in view, the water-front being simply one large window. Music, singing, and speeches came in between the courses, and at the close the whole party was taken by boats to the Tivoli gardens, about a mile distant, where there was a grand illumination, a concert, fireworks, etc. Taking it altogether, this entertainment

surpassed anything of the kind which has occurred at any previous Congress.

I shall not occupy more space with descriptions of the social features of the Congress, and will only say that they have been all that could be desired. A good, plain, simple lunch has been provided every day for the members of the Congress on a plan essentially the same as that followed at Philadelphia in the Congress of 1876.

With regard to the scientific work of the Congress, the general feeling is that it has been satisfactory both in quantity and quality. This, however, the readers of THE MEDICAL NEWS can judge for themselves when reading the reports of the proceedings of the several Sections.

With regard to the next place of meeting of the Congress, there was at first considerable difference of opinion. It was known that an invitation would be extended from America, and the English, Scotch, and Irish members were in favor of its acceptance. The French and some of the German members did not wish to accept it, because of the time and expense required, and also from fear of sea-sickness. Virchow desired to have the next Congress at Berlin; but no formal invitation was presented, and the general feeling, even among German physicians, seemed to be that the time has not yet come for the Congress to go to Berlin. An invitation was presented from Rome; but Italy has already had one Congress, and Rome is very malarious in August and September. St. Petersburg was also talked about; but after the formal invitation from American physicians was presented to the Congress by Dr. Billings, it became evident that it would be accepted, and this was accordingly done on the last day with general applause. Many of the prominent members of the Congress declare their intention of going to Washington in 1887, and it is probable that, when the time comes, most of them will carry out this purpose.

The American Committee of Organization for the Washington Congress will have a difficult task before it, and it will require the support of the whole profession of the country to make it such a success as it ought to be made; but if American physicians take hold of the matter in earnest, there can be no doubt of the result. If the members of that Congress leave Washington as well satisfied as the members of the present Congress, taken as a body, feel in leaving Copenhagen, it will be a great success.

(*From another Correspondent.*)

COPENHAGEN, August 16, 1884.

The Eighth Session of the International Congress opened at Copenhagen, according to programme, in the presence of their Majesties, the "Kongen of Danamark and le Roi des Hèllenes," on Sunday, August 16, at 1 P.M., with all the pomp and glitter of a regal ceremony. The Exposition building was gaily decorated with flowers and graced with the flags of all nations as the assembled delegates and visitors crowded into the hall. The whole array of Denmark's livery was on the street in front, where were gathered, to witness the imposing spectacle of the arrival of two kings, such a multitude of people as to keep the police busy in clearing the road.

Every member of the Congress had had put into his hands before arrival at the hall a greeting on the part of the civil authorities, in the form of a paper faced with a very good portrait of Pasteur, who is evidently the hero of the hour, as all the prominent shop-windows display his picture in the most conspicuous place. Photographs of Sir William Paget, Gull, Esmarch, Donders, Virchow, Chauveau, Axel Key, Koch, and others are also to be seen here and there. The greeting appears in the Danish, German, French, English, and Italian languages, and declares a cordial welcome to all the guests. The salutation runs as follows:

"*To the Eighth International Medical Congress:*

"The Danish medical state, the citizens of Copenhagen, and the entire Danish people do, to-day, welcome the Medical Congress in the capital of Denmark.

"It is with a feeling of pride that Copenhagen welcomes the celebrated representatives of one of the most advanced sciences.

"The medical science with its humane purposes has, in preference to all other sciences, a specially international character. No other profession than the medical is at the same time so deeply connected with the daily life of mankind and with the highest problems of human knowledge, no other calling has to a higher degree made itself deserved of suffering humanity and more contributed to softening the evils that are the unavoidable consequences of growing civilization.

"It is with gratitude that the Danish medical men, in the name of the whole people, have accepted the appeal to become hosts of the Eighth International Medical Congress. This honor involves, that the great world does not look upon Denmark as a country so distant from the great thoroughfare of civilization that it should be unable to find a place of meeting large and rich enough to give room for its studies, so fertilizing and blessing to mankind.

"Denmark, certainly, does not rank high in the council of the nations of the world, yet in our little country constantly reigns a feeling of the necessity to small nations of trying their utmost to keep pace with the other nations, where not the material but intellectual faculties are dominating. Denmark can, with a just feeling of pride, point to a number of men in more than one respect deserving well of mankind. Denmark is able, if it be not in every respect, to display scientific institutions, not grand, perhaps, but nevertheless institutions up to the claims of modern science.

"It is with these feelings that the Danish government, the Danish people, the magistrates of Copenhagen, and our medical men greet the bloom of the medical state of the civilized world, and it is with the fullest assurance that from all parts, high and low, there will be shown our guests every kind of friendliness and hearty welcome.

"A welcome to the members of the Medical Congress."

After a speech of welcome by Prof. Panum, President of the Congress, the lions of the occasion were put on exhibition with short addresses, Profs. Virchow, Paget, and Pasteur, eliciting the heaviest rounds of applause.

Foreign members of the Congress suffer great inconvenience from their inability to learn from the newspapers anything that has been done in the Sections

which they have been unable to attend. For there is no daily paper published in Copenhagen, a city of 300,000 people, in any other language than the Danish. Since the appropriation by Prussia of Schleswig-Holstein, the biggest half of Denmark, a deep feeling of animosity is cherished against the Germans everywhere: in Copenhagen, all German papers have been suppressed. In any American city the Congress itself would issue daily reports of the proceedings of the day before, but here there is nothing but the bulletins announcing the work of the day. The consequence is no one not understanding Danish can be informed of the work of any Section other than the one he attends.

THE MEDICAL SECTION

met in an upper lecture-room of the University building, and opened with a report by PROF. AUSTIN FLINT *On a Uniform Nomenclature of Auscultatory Sounds in the Diagnosis of Diseases of the Chest.*

At the meeting of the International Medical Congress, in London, in August, 1881, the following resolution was adopted by the Section of Medicine:

Resolved, That a committee be appointed to report to the Medical Section of the next Congress, wherever it may meet, on a uniform nomenclature of auscultatory sounds in the diagnosis of diseases of the chest. The following were appointed members of this committee:

Prof. Austin Flint, of New York, Chairman. Prof. Ewald, of Berlin; Prof. d'Espine, of Geneva; Dr. Douglas Powel, of London; Dr. F. A. Mahomed, of London.

At a meeting of this Committee in London, it was agreed that each member of the Committee should send a report to the Chairman, and the Chairman engaged to send to each member the several reports, or an abstract of them, the subsequent report of the Chairman to the Congress to be based on the reports collectively.

The Chairman of the Committee has received reports from each member of the Committee. The result of the comparison of the several reports is a very close approximation to a uniform nomenclature of auscultatory sounds. The points of difference relate to the following sounds, as regards either the names or their definition:

1. The respiratory sound denoting pulmonary cavity.

2. The dry and moist adventitious sounds produced within the bronchial tubes.

3. The scope of the terms crepitation, râles crépitants, Knisterrasseln.

Dr. Flint read only the conclusions of his report, and presented for inspection the following tabulated lists of terms to be used as synonyms in all lands.

Criticisms upon this report having been made by a number of members, it was decided to adopt this list as a provisional report, to continue the same Committee, to enlarge it by the addition of members from other lands, and to dispose of the subject at the next annual session.

DR. S. LAACHE, of Christiana, then read a paper on the *Value of the Later Investigations of the Blood Corpuscles in Anæmia and Leukæmia.*

The value of these researches lies in the great precision with which anæmic conditions can be understood. By means of the changed and much simplified methods of Vierordt and Welcker, and, later, of Malassez and Hayem, the clinician can now determine with tolerable certainty not only the relative number of the corpuscles, but also the coloring power of the blood, whilst formerly these could only be recognized in an uncertain degree.

In anæmia after hemorrhage both the number of the red corpuscles and the amount of hæmoglobin in the blood may be far less than fifty per cent. without causing immediate death, and without restitution to health being impossible, even though new blood be not added by transfusion. During the process of regeneration the formation of new hæmoglobin does not take place so rapidly as that of the red disks. In other cases of secondary anæmia the decrease, by complicating hemorrhages, of the coloring matters of the blood is generally but little proportional; cancer is an exception, though only in this case when the general state of nutrition of the patient is essentially changed.

In chlorosis two forms must be recognized, according to the proportion of the red disks: the one with either no, or only a very unimportant affection of the red disks—pseudochlorosis; and the second, true chlorosis, in which the red disks are affected, and sometimes very considerably. In chlorosis not only is the coloring power of the blood reduced to a greater or less degree, but also the number of the red corpuscles, the former being generally most affected. The distinction of these two forms is important, since it is in true chlorosis that iron exerts its well-known action. This is due to the fact that by the use of large doses of iron an active formation of new red disks and hæmoglobin, especially of the latter, takes place.

In pernicious anæmia the number of the red disks falls below 500,000 per cub. mm. without causing death, and without the impossibility of restitution to health. The proportion of the red disks is, in this disease, greater as a rule, and they contain more hæmoglobin than is normally the case.

Whilst the proportion of the white corpuscles in all

PALPATION.

BRITISH LIST. DR. POWELL AND DR. MAHOMED.	AMERICAN LIST. DR. AUSTIN FLINT.	GERMAN LIST. PROF. EWALD.	FRENCH LIST. PROF. D'ESPINE.
1. Vocal fremitus.	Vocal fremitus.	Stimmfremitus, oder Vocalfremitus.	Vibrations thoraciques.
2. Rhonchal fremitus.	Rhonchal fremitus.	Rhonchofremitus, oder Bronchialfremitus.	(Not included.)
3. Friction fremitus	Friction fremitus.	Pleuritisches resp. Pericarditisches Reiben.	Frottement.

PERCUSSION.

1. Tympanitic resonance.	Tympanitic resonance.	Tympanitischer Schall.	Son tympanique. (*a*) grave, (*b*) élevé.
2. Amphoric resonance.	Amphoric resonance.	Metallklang.	Bruit de pot fêlé.
3. Diminished resonance. Dulness.	Diminished resonance. Dulness.	Dämpfung.	Submatité.
4. Absence of resonance. Flatness.	Absence of resonance. Flatness.	Absolute oder starke Dämpfung.	Matité.
5. Increased resonance.	Increased or vesiculo-tympanitic resonance.	Hypersonorer Schall.	Son pulmonaire exagéré.
6. Bell sound.	(Not included.)	(Not included.)	(Not included.)

AUSCULTATION.

First Group. Varieties of Breath Sounds.

1. Exaggerated Syn. Puerile. Compensatory. Supplementary.	Exaggerated, etc.	Verschärftes Athemgeräusch.	Respiration exagérée.
2. Diminished. Syn. Feeble. Weakened vesicular murmur.	Diminished, etc.	Abgeschwächtes Athemgeräusch.	Respiration diminuée.
3. Suppressed. Syn. Absence of breath sound.	Suppressed, etc.	Fehlendes Athemgeräusch.	Respiration supprimée.
4. Prolonged expiration. General or local.	Prolonged expiration. High or low in pitch.	Verlängertes Exspirium.	Expiration prolongée.
5. Interrupted inspiration. Syn. Jerking, wavy, cog-wheeled.	Interrupted respiration, etc.	Saccadirtes Athemgeräusch.	Respiration saccadée.
6. Tubular. Syn. Bronchial. High-pitched blowing.	Tubular. Bronchial, etc.	Bronchiales Athemgeräusch, (*a*) stark, (*b*) tief.	Souffle bronchique, (*a*) superficiel, (*b*) profond, (*c*) doux, (*d*) fort.
7. Vesiculo-tubular. Syn. Broncho-vesicular. Harsh, coarse, subtubular.	Broncho-vesicular. Syn. Vesiculo-tubular.	Unbestimmtes Athemgeräusch.	Respiration rude, broncho-vésiculaire.
8. Amphoric.	Amphoric.	Amphorisches Athemgeräusch.	Souffle cavitaire amphorique avec écho musical ou métallique.
9. Cavernous.	Cavernous.	(Not included.)	Souffle cavitaire simple ou sans écho musical.

Second Group. Adventitious Sounds.

1. Rhonchi. Dry musical sounds. (*a*) Sonorous, (*b*) Sibilant.	Rhonchi or dry bronchial râles. (*a*) Sonorous, (*b*) Sibilant.	Rhonchi. Trockene Rasselgeräusche. (*a*) sonor (schnurrend), (*b*) sibilans (pfeifend).	Ronchus. Râles secs. (*a*) Ronflants, (*b*) Sibilants.
2. Stridor.	Stridor.	Stridor. Stenosengeräusch.	Sifflement laryngé. Bruit de cornage. (*a*) Trachéal, (*b*) Bronchique.
3. Râles. Syn. Bubbling râles, etc. (*a*) Medium, (*b*) Large. High or low in pitch.	Moist or bubbling râles. (*a*) Large, (*b*) Medium, (*c*) Small. High or low in pitch.	Feuchte Rasselgeräusche. (*a*) grossblasige, (*b*) mittel grossblasige, (*c*) kleinblasige.	Râles humides. (*a*) Gros, (*b*) Moyens, (*c*) Fins. (*a*) A timbre bronchique, (*b*) Sans timbre ou simple.
4. Gurgling.	Gurgling.	Höhlenrasseln.	Gargouillement.
5. Clicking.	Clicking.	(Not included.)	Craquements. (*a*) Secs, (*b*) humides.
6. Crepitation. Syn. Crepitant râle.	Crepitant râle or crepitation.	Knisternde Rasselgeräusche, Knisterrasseln.	Râles crépitants.
7. Metallic tinkling.	Metallic tinkling.	Metallisches Rasselgeräusch, Metallklang.	Tintement métallique.
8. Splash.	Splash.	Succusionsgeräusch.	Succussion Hippocratique.
9. Friction. (*a*) Dry, (*b*) Moist.	Friction.	Reibegeräusch.	Frottement.

Third Group. Varieties of Voice Sounds.

1. Increase of vocal resonance.	Increase of vocal resonance.	(Not included.)	Voix exagérée.
2. Diminution or absence of vocal resonance.	Diminution or absence of vocal resonance.	Abschwächung und Fehlender Stimme.	Voix diminuée.
3. Bronchophony.	Bronchophony.	Bronchophonie.	Bronchophonie.
4. Pectoriloquy.	Pectoriloquy.	Pectoriloquie.	Pectoriloquie.
5. Ægophony.	Ægophony.	Ægophonie.	Egophonie.

The lists are arranged in the order of their reception.

the above-mentioned states is inconstant, their increase in leukæmia is a predominating symptom of this disease. Their size is, as a rule, much changed. The red disks may be of normal proportions even in vigorous development of the disease; and the reduction of their number does not necessarily reach the extreme degrees of the three diseases spoken of above, even when the disease has lasted a year.

Prof. Tommasi-Crudeli, of Rome, followed with a discourse, illustrated by drawings and microscopic preparations, on the subject of *Malaria*, dwelling upon the bacillus malariæ and more especially upon its influence in dissolving and disintegrating the protoplasm of the blood corpuscles, liberating the hæmoglobin to be deposited in the brain and elsewhere. Though the paper was interesting, it contained nothing especially new to those familiar with the works of Cuboni and Marchiafava.

The Section now adjourned to hear Pasteur on the subject of *Microbes Pathogènes et Vaccins*, in an address which contained no contributions to his work with which your readers are not already thoroughly familiar.

Pretty much the whole of the second day was taken up with *Tuberculosis*. The honor of introducing this subject was entrusted to PROF. EWALD, the accomplished editor of the *Berliner klinische Wochenschrift*.

Prof. Ewald took as his title *The Etiology, Diagnosis, Prognosis, and Treatment of Tuberculosis in Reference to Recent Researches in Pathological Anatomy and Experimental Pathology*, and in his paper which was really too long for such an occasion, covered the whole vast field thus announced. He commenced with the statement that the bacillus, which should only be called after its discoverer, the bacillus Kochii, was the sole cause of tuberculosis, and whoever would now deny this fact would place himself out of the limits of discussion. Scrofula, lupus, perlsucht, were only other forms of the same disease, and though clinically distinct had the same pathogeny. The question of predisposition and heredity was also exhaustively treated, but nothing was expounded different from accepted views. It was not true that the number of bacilli in the sputum afforded always a fair prognosis of tuberculosis, as the number present may be a matter of accident. In prophylaxis stress was laid upon the destruction of the products of the disease as well as upon the rejection of the milk and flesh affected with the perlsucht. There was nothing new in the way of treatment, as, indeed, there could not be without the speedy knowledge of it throughout the world.

After Ewald, came PROF. JACCOUD, of Paris, with a paper on the *Treatment of Tuberculosis*. It was quite a treat to hear Jaccoud. His articulation is clear and distinct, his voice penetrating and finely modulated, his manner animated, it would be more fair to say vivacious. Jaccoud made what the country students with us would call a ringing speech, and I doubt if the halls of the sleepy old University (I mean no detraction to the splendid scholars of this land) ever before resounded to the echoes of such eloquence. I have myself heard the best speakers in all lands, but I have never listened to such a declamation as this before, *ex cathedra medicale*. His peroration received an ovation of applause. It was curious to observe the excitement to which this staid, I had almost said phlegmatic, assembly was stirred under the stimulus of such an earnest appeal.

But in glancing over the hall it was easy to see that the interest on the part of some of the members was rather psychological than real, evincing a surprise rather than a pleasure at witnessing such a phenomenon in a hall of science. For the whole tenor of the speech was to the effect that while the discovery of the bacillus was a brilliant accomplishment, it had contributed nothing to the cure of the disease. The speech closed with a glowing tribute to the genius of Pasteur, who was present at the time, and indicated that studies pursued in the direction which he had pointed out would yield most practical results.

The discussion upon this subject was postponed until all the papers upon it had been read.

DR. GRANCHER, of Paris, now took the stand to read his paper on the *Diagnosis of Pulmonary Tuberculosis in the Early Stage*. He stated that pulmonary tuberculosis is always very difficult to diagnosticate in the early stages. The sources of medical diagnosis are, however, numerous, and have been recently enriched by the discovery of the tubercle bacilli in the sputa. In pulmonary tuberculosis of pneumonic form, when softening is very rapid, the bacilli may be found when the diagnosis rests on the physical signs and is yet doubtful. The same is true when pulmonary tuberculosis begins with hæmoptysis, or is concealed under the symptoms of diffuse bronchitis, with or without pulmonary emphysema. The presence of the tubercle bacilli is, then, the best of all signs.

But when the tubercles develop silently, and softening is very slow—which is most commonly the case—when the patient begins to cough and expectorate only after the disease has lasted for some time, the bacilli only appear in the pus of the sputa when their presence is superfluous for the diagnosis. The bacilli, when present, may be very rare and escape notice in a microscopical examination, but they are present in sufficient numbers to produce inoculation in guinea-pigs. Hence we have a method of diagnosis founded on the positive or negative results of inoculation. This method, however, requires some time (one or two months, and more if the results of the first inoculation are doubtful, and control-experiments are necessary); even in this there may be causes of error, as it is necessary, for the success of an inoculation, to have at least one bacillus in the inoculating material, and in these cases the diagnosis should be made before the bacilli can be found. But the physical signs are sufficient for a probable diagnosis at first, and later for a certain diagnosis.

Grancher has, in several cases, followed the evolution of the physical signs from the very beginning of the disease to the period of softening. Commencing with an alteration in the softness of the inspiratory murmur, and with a lowering of its tone, it is followed, even after a long stationary period, by prolonged expiration, and then, later, by bronchophony, diminished resonance, and expectoration. This process may last for three or four years or more. The progressive decrease in strength, emaciation, the cough, sputa, and other symptoms run a parallel course with the physical signs.

At what time can the diagnosis be made? Should we wait until percussion and palpation give positive results? Or can we, under certain circumstances, diagnosticate the presence of tubercles by the single alterations in the respiratory murmur? If the certainty of the diagnosis increases proportionally with the physical signs, the gravity of the disease also increases; for the slight dulness and bronchophony correspond to the accumulation of tubercles, or, in other words, to the age of the softening. Every variety of anomalous respiration (the interrupted, feeble, rude) may be indicative of commencing tuberculization. But in Grancher's opinion, rude respiration with lowered tone of the *inspiratory* murmur is the earliest and best of the physical signs at the commencement of pulmonary tuberculosis. This respiratory anomaly is, in his opinion, sufficient, when it is clear, localized at the apex of the lung, and when the *terrain* is suspicious (rebellious chloro-anæmia, scrofula, heredity, etc.), to give a probable diagnosis.

This alteration of the subclavicular murmur is shown, at the commencement of the disease, more often on the left side than on the right, which confirms the opinion

of those who think that, as a rule, tuberculosis of slow development commences on the left side; and diminishes the value of this symptom for those who think that the normal vesicular murmur is stronger in the left subclavicular region than the right. Grancher does not believe that there is any constant physiological difference in this respect on the two sides, but a transient or slight influence, a fugitive congestion at the time of the menopause for example, may alter the murmur on one side or the other. One should not, then, hasten to make a diagnosis of tuberculosis on the first discovery of rude inspiration, but this sign should lead to suspicion when it persists, and when rational symptoms are found on suspected *terrain*. Under these circumstances a probable diagnosis should be made, and the physician should at once begin treatment.

Dr. Quinlan, of Dublin, followed next with a paper on *The Use of Mullein in the Treatment of Tuberculosis*, for which he claims such wonderful results, as to have attracted to his hospital great crowds of patients. Dr. Quinlan passed around the house a gigantic specimen of the mullein over six feet in height, and distributed among the members several boxes of cigarettes made of its leaves. The principal points of his paper were as follows:

The Library of the Royal Irish Academy in Dublin contains a large number of manuscripts in the Celtic language, and treating upon medical subjects. Constant mention is made of the "cuineal mhuire" as a remedy in pulmonary diseases, and this plant has the most extraordinary reputation in the Celtic portions of the United Kingdom, and especially in Ireland, as a palliative and even curative remedy in cases of pulmonary consumption. In Ireland, although unrecognized by the medical profession, it has been for centuries given upon an immense scale in obedience to a steady demand on the part of phthisical sufferers; and during the last two years he undertook a scientific investigation as to its alleged powers, the highly satisfactory result of which he submitted to the Congress.

This plant is known to botanists as the Verbascum thapsus, and belongs to the natural order of Scrofulariaceæ. Its English name is the Great Mullein; in France it is known as Molène Bouillon Blanc, and in Germany as Kleinblumiges Wollkraut. The mode of using it is to place ʒvij of the dry leaves, or, much better, ʒiij of the fresh, in a pint of new milk, to boil and allow to stand for ten minutes, then to filter and add a little sugar. This whole mixture is to be drunk morning and evening.

A large number of cases of pulmonary consumption have been treated in St. Vincent's Hospital, Dublin, exclusively upon mullein. These cases were all carefully tabulated and the patients weighed once a week, great care being taken to insure conformity of conditions in this respect. The results arrived at are as follows:

1. In the early and pretubercular cases of the disease Mullein is weight-increasing and curative to a much greater extent than koumiss or cod-liver oil.

2. In advanced cases it does not cure, but gives greater relief to phthisical cough and prevents or checks phthisical diarrhœa.

3. It has no effect upon the colliquative perspirations of phthisis.

4. In phthisical coughs and in spasmodic coughs generally great relief can be obtained by smoking mullein leaves in the same manner as tobacco.

This can be effected either in an ordinary pipe or by means of cigarettes. On the dried mullein leaf powder a very weak solution of potassium nitrate is sprinkled and flavored with oil of cascarilla. These cigarettes are rolled in paper in the ordinary way, and are very pleasant to smoke. Mullein has been tried in watery infusion, but is disagreeable. The same remark applies to the extract or succus.

It may be said that the weight-increasing effects were due to the milk; but experience shows that this was not so. It is greatly liked by the phthisical sufferers.

Dr. R. Shingleton Smith, of Bristol, came next in order with a paper on *The use of Iodoform in the Treatment of Phthisis*.

After a short review of the history of iodoform as a drug for internal administration, the author gave an analysis of the results of treatment in forty-six cases arranged in tables to show the variation in weight before and after treatment: in twenty-nine out of the forty-six cases, there was an absolute gain in body-weight, amounting in one case to thirty-two pounds, and in another to thirty-three pounds. Other indications of improvement were fall of temperature, diminution of cough and expectoration, cessation of night-sweats, improved appetite. The drug was given in doses varying from one to six grains five times daily, and was continued for several months. Toxic symptoms of a mild character had been observed in some of the cases. The paper concluded with a reference to the local use of iodoform in tuberculous disease of the larynx.

The afternoon was devoted to the discussion of the papers read.

Remarks were made first by Dr. Guttmann, of Berlin, who made the very good point that they were as familiar in Berlin as in Paris with the fact that the discovery of the bacillus tuberculosis did not cure consumption, and that they were acquainted with another fact, to wit—the reason why no remedy has been found to reach the disease, viz., because the bacillus tuberculosis, as the result of a great many experiments, proved to be more resistant to destructive agents than the tissues in which it was found.

Dr. Pibbram, of Prague, paid a glowing tribute to Koch, and remarked that the discovery was as yet of too recent date to furnish practical results.

Dr. Crocq, of Brussels, followed in a very curious speech, discrediting all previous theories and facts, and declaring one of his own. The remarks were delivered in very voluble French, and as it is quite difficult to follow idiosyncrasies in a foreign tongue, I failed to make out exactly the author's views.

The remarks of the last speaker extended over so much time that the discussion was called to a close, with permission to Dr. Ewald to make a short response, which was delivered in very good French, and chiefly expressed the satisfaction of the speaker at the unanimity of opinion regarding the fact of the existence and the causative relation of the bacillus of Koch. He could not respond to Dr. Crocq, he said, as this gentleman was not in accord with any of the recent views.

DR. BRANDES, of Copenhagen, now presented a case of *Myxœdema*, and made some remarks upon the pathology of this affection.

SIR WILLIAM GULL, of London, in the discussion which followed, was inclined to consider the case as one of simple cretinism in the adult. This affection, he said, is usually believed to be a disease of childhood only, but, in the speaker's opinion, existed or developed also in adult life.

DR. MAHOMED, of London, did not regard myxœdema as a disease of the thyroid gland alone, or as an affection of any one part of the body. It was the expression of a perverted nutrition, the result of affection of the nervous system from many different causes. He instanced two cases of recovery from the disease, and spoke of post-mortem examinations in which capsulitis of the liver was found, but no increase of mucin in the tissue affected.

The afternoon session closed with a paper by DR. JOSEPH EWART, of London, on *The Treatment of Chronic Diarrhœa and Dysentery in Persons returned from Tropical to Temperate Climates, by Milk Diet.*

SURGICAL SECTION.

(*From our Surgical Correspondent.*)

NORTH SEA, S. S. RONA, August 16, 1884.

On Monday the 12th, PROF. PLUM, of Copenhagen, took the Chair, and in a few feeling words spoke of the recent sad death of Dr. Holmer, who was to have been President of the Section. He called on Sir Henry Acland, of Oxford, to say a few words regarding him.

SIR HENRY ACLAND spoke of when he first made Holmer's acquaintance at a time when, as a stranger to Copenhagen, he needed the aid of a medical man. He spoke of Holmer's kindness, gentleness, and skill, and said that it was with some difficulty that he came to Copenhagen after he heard that Dr. Holmer was dead. He expressed, in the name of the strangers present, the deep regret that they felt for the loss of so distinguished a man, and he conveyed to the Scandinavian members of the Section the sympathy that was felt for them by their guests.

After the election of Vice-Presidents and Secretaries, Prof. Plum asked Prof. Volkmann to take the Chair.

PROF. ESMARCH, of Kiel, then read a communication on *Extirpation of the Cancerous Rectum.* After speaking generally of the pathology of cancer, the writer pointed out the danger of delay in operating on cancer of the rectum and the necessity for complete removal. Hemorrhage was checked by the use of the double ligature, all bands being tied before division. Sepsis was avoided by packing with sublimate gauze. Drainage and the escape of feces were obtained by the introduction of a large tube. The peritoneum was often opened when the tumor was situated high up. The mortality of the operation is about twenty per cent. The anus and sphincter were left, no stitches were used, and there was no necessity for excision of the coccyx to give space.

MR. BRYANT, of London, then read a communication on *Lumbar Colotomy as a Curative and Remedial Operation in Syphilitic, Simple, and Cancerous Ulceration of the Rectum and Colon, with an Improved Method of Performing the Operation.*

This paper is based upon Mr. Bryant's personal experience of eighty-two cases. It includes an analysis of the cases, and affords evidence which the author deems conclusive in support of the following propositions:

1. That in all cases of cancerous stricture of the rectum or colon, including the annular—which are not amenable to lumbar *colectomy* or anal excision—right or left lumbar colotomy is strongly to be advocated with the well-grounded hope of relieving suffering, retarding the progress of the disease, and of prolonging life even for five or six years.

2. That lumber colotomy is valuable as a *curative* operation in syphilitic and simple ulcerations of the bowel which resist other treatment, including cases of recto-vesical fistula; and that it is remedial in examples of volvulus of the sigmoid flexure, as well as of obstructions caused by tumors.

3. That to secure these advantages, it is necessary for the operation to be performed before the pernicious effects of obstruction occur.

The details of the improved method of performing the operation were also given.

Mr. Bryant then gave the following analysis of the whole number of eighty-two cases of colotomy: 60 were performed for cancerous stricture; 19 were performed for stricture and ulceration of the rectum not cancerous; 1 was performed for volvulus of the sigmoid flexure of the colon; 2 for obstruction due to pelvic tumors.

Side operated upon: Left lumbar colotomy was performed in 77, and right lumbar colotomy in 5 of these cases, all of the five being cancerous. Right lumbar colotomy was called for in 1 out of 12 cases of cancerous stricture.

Duration of life after the operation: 26, or 43 per cent. of the cancerous, and 6, or 31.5 per cent. of the non-cancerous cases, with one of the cases operated upon for obstruction, or 40 per cent. of the whole number of 82 cases operated upon, died within the month.

34, or 56 per cent., of the cancerous, and 13, or 68.5 per cent. of the non-cancerous cases, with the case of volvulus and one of the cases of obstruction, or 60 per cent. of the whole number of cases operated upon, received more or less fully the benefit of the operation.

Of the forty-nine successful cases:

16 cases, 9 cancerous, and 7 non-cancerous, died within 6 months.					
8	" 7	"	1	"	lived from 6 to 12 months.
12	" 9	"	3	"	lived from 1 to 5½ years.
5	" 1	"	4	"	were alive from 1½ to 14 years after operation.
8	" 8	"	had left the hospital convalescent.		
49	34		15		

Sex.

Of the 60 cancerous cases:	40 were in males,	20 in females.	
" 19 non-cancerous:	10 "	9 "	
1 case of volvulus:	1 was in male.		
2 cases of obstruction:	1 "	1 in female.	
Of the 82 cases:	52 were in males,	30 in females.	

Cancerous stricture is more frequent in males. Non-cancerous stricture is found equally in both sexes.

Age.

The average age of the cancerous case,
When fatal was 53: in male subjects 54, in female 51.
" successful 44 " 46 " 41.

The average age of the successful being about 10 years less than that of the fatal cases.

No abnormality as to the position of the colon was met with in any of the 82 cases.

Prof. Verneuil, of Paris, opened the discussion. He began by saying that he performed his first case of excision of the rectum fifteen years ago, his first colotomy thirty years ago. He believed complete removal to be difficult, and recurrence after operation frequent, and his patients objected to colotomy. He thought all the painful symptoms were most easily relieved by making an artificial channel from the tip of the coccyx, with the thermo-cautery, to a point in the rectum above the stricture. He then passed the chain of an écraseur along this channel and brought it out at the anus, by which means he was enabled to divide the strictured part and sphincter bloodlessly and without danger to life.

Mr Sampson Gamgee, of Birmingham, thought inguinal colotomy the preferable operation, but each case must be judged of by itself. No general rule will suit all cases.

Mr. Marshall, of London, spoke of the value of the method of relief recommended by Prof. Verneuil.

Prof. Volkmann, of Halle, thought excision safer than colotomy. He spoke of the slow growth of cancer of the rectum, and the long time that elapsed before the glands became affected. He believed the comfort to be greater after excision than after colotomy. He never operates in cases in which he cannot reach the upper end of the disease. He gave chloroform and examined by the bimanual method before operating. No attempt was made to stitch the upper to the lower end.

Mr. Henry Morris, of London, spoke of the value of lumbar colotomy, and presented statistics of his practice.

Prof. Kuster, of Berlin, spoke of the value of iodoform as a dressing after excision of the rectum.

Prof. Paquet, of Lille, showed an example of *Hypertrophy of the Upper Jaw Removed by Excision and the Upper End of the Femur Removed in a Case of Amputation of the Hip-joint with the Thermo-cautery.*

Mr. Reginald Harrison, of Liverpool, then read his paper on *The Treatment of Certain Cases of Prostatic Obstruction by Section of the Gland.*

This class includes cases in which there is unusual difficulty in introducing the catheter, in which the withdrawal of the urine is followed by no sense of relief, and in which the bladder, by the constant presence within it of pus and tenacious mucus, is converted into little else than a chronic abscess through which urine percolates. These, as well as some other forms of prostatic disease which might be included, are practically unrelievable by the catheter, and speedily terminate in painful death. He had been impressed with the advantage that followed the judicious employment of suitable bougies as dilators in cases in which the prostate threatened to obstruct micturition.

Influenced by observations of this kind, he was led to attach considerable importance to the treatment immediately following section of the obstructing portion of the enlarged gland with the view of rendering the latter more permanent than had hitherto been attempted.

The operation consists in opening the membranous urethra from the perineum on a guide, and introducing the finger within the prostatic urethra. The obstructing portion of the gland is then divided in the median line, partly by incision with a straight probe-pointed knife, and partly by divulsion with the finger or large-sized bougie until the access to the bladder is felt to be free. In doing this operation it is not desirable to make an opening larger than will admit the index finger from the perineum into the bladder, such an opening is completely filled up by the drainage-tube that is subsequently used, and consequently but little risk of hemorrhage need be entertained.

The drainage-tubes Mr. Harrison is in the habit of employing after section of the prostate has been effected are gum-elastic, with a special provision for the more thorough drainage of the bladder than has hitherto been attempted. This consists in the employment of a double tube. He attaches very considerable importance to the prolonged use of the drainage apparatus, as his object is to render the section of the prostate not a temporary one, as after a lithotomy where no such provision is made, but permanent. Hence he is in the habit of retaining these tubes for six, eight, ten, or twelve weeks. If after such periods, on removing the tube, he finds that a catheter can be made to enter the bladder easily along the natural route, or if, as it sometimes happens, urine forces its way in spite of the perineal tube along the natural passage, he regards these as indications that the object in view in the retention of the drainage-tube has been obtained. The regular use of the bougie is continued until the perineal wound has soundly healed, a process which usually takes place rapidly, and leaves but little mark. As a precautionary measure, patients are enjoined to continue to use the bougie occasionally.

It will be observed that section of the bar is preceded in all instances by a careful digital exploration of the prostatic urethra, with the view of directly determining the nature of the obstruction and the direction of the incision to remove it.

In some instances, in which stone in the bladder has been secondary to the formation of a prostatic bar and the incomplete emptying of the bladder, lithotomy has been selected as affording opportunity, not only for the removal of the stone, but the bar which led to its formation. In a case of recurring stone, this operation has been followed by the continued excretion of urine of an acid reaction, when after previous lithotrities the urine was invariably alkaline.

In offering an explanation of the results obtained, Mr. Harrison thinks we have it, not only in the means which are adopted to render the section of the prostate permanent, but further, he believes something is due to the introduction into the prostate of no inconsiderable quantity of shrinking or cicatricial tissue.

Prof. Volkmann spoke of the value of a perineal median opening with drainage, without dividing the prostate gland.

On Tuesday, at 9.30 A.M., Professor Sayre, of New York, gave a demonstration to a large audience of continental surgeons on his method of applying *The Plaster Jacket in Cases of Pott's Disease of the Spine and in Lateral Curvature.* This demonstration was completed on Friday at the same hour; a case in which he had

applied the jacket on Tuesday being then brought forward with the jacket in a finished condition.

At 10 A.M. Mr. Thos. Bryant, of London, took the Chair, and Professor Ollier read a paper on *Excision and Arthrotomy in Tuberculous Joint Disease*. He recommended in those cases free removal of all diseased tissue, care being taken, by cauterization of the joint, to prevent tension. The sharp spoon and cautery were freely used to remove and destroy all diseased tissue.

Dr. Lowenstein, of Hamburg, showed a case in which he had *Excised an Ankle-joint* after the method of Mikulicz. The disease was completely removed, and the result closely resembled an aggravated case of talipes equinus.

Professor Skliffosowski, of Moscow, related his experience of such cases, and recommended a similar treatment.

Dr. MacEwen, of Glasgow, read a paper entitled *Osteotomy for Genu Valgum*. He brought forwards a large mass of statistics showing that the supracondyloid operation associated with his name had obtained the approval of a large majority of the profession, and that the operations of Ogston, Chiene, and Schede had been used by comparatively few British surgeons.

Professor Ogston, of Aberdeen, said that he would now use MacEwen's method in preference to his own; and Professor Chiene, of Edinburgh, promised to give it a fair trial. Dr. Schede said that in some cases he believed division of the tibia to be necessary.

Dr. Robin, of Lyons, exhibited an ingenious *Instrument for Fracturing the Femur above the Condyles*. In the specimens he showed that the line of fracture was at a higher level than where the bone is divided by MacEwen.

Mr. W. Adams, of London, demonstrated, by a series of photographs taken from cases of *Dupuytren's Finger-contraction*, the method which he preferred, by subcutaneous division of the fascia at many points, in the treatment of such cases.

In the afternoon a discussion took place on Professor Ollier's paper. This discussion was opened by Professor Chiene, of Edinburgh, and Professors Volkmann and Trélat took part in it. The opinion of Volkmann and Trélat was that the diseases of bone near joints were almost always tubercular, and that free removal of the diseased tissues was necessary in order to prevent generalization of the disease throughout the body.

Dr. Howe, of New York, showed a *Calculus* over eight ounces in weight which he had *Removed by the Suprapubic Operation* from a boy. The boy recovered satisfactorily. The peritoneum was wounded.

On Thursday, August 14th, Professor Trélat, of Paris, took the Chair. It was hoped that Professor Lister would open the discussion on antiseptic surgery; much regret was expressed at his absence, and President Plum spoke of the honor that they, as surgeons, owed to Professor Lister.

Professor Esmarch read a paper on the *Permanent Antiseptic Dressing*. He spoke of Lister as the master and teacher of them all. He desired: 1. Avoidance of suppuration. 2. Non-disturbance of the wound. 3. Exact hæmostasis. 4. Avoidance of cavities. 5. Drainage by leaving an opening between the stitches. Artificial ischæmia, catgut ligature, washing during operation with solution of salt in distilled water, afterwards with corrosive sublimate lotion. After applying deep stitches he applied peat pillows, no mackintosh, and lastly soft bandages, fixing the parts with glass bandage. This dressing was kept on for ten days or a fortnight.

Professor Mosetig v. Moorhof, of Vienna, read a paper on the *Iodoform Treatment of Wounds*. He used iodoform and nothing else, and simple water as a wash.

Dr. Schede, of Hamburg read his paper on *The Sublimate Treatment of Wounds*. He used no other antiseptic, and gave statistics of his results. He had had no poisoning since using 1 in 2000 to disinfect and 1 in 5000 as a lotion. He used glass wool instead of protective-sublimate moss as a dressing.

Professor Mikulicz, of Krakow, used iodoform in the cavities of wounds lined with much membrane.

In the discussion which followed, Prof. Neudorfer laid special stress on dryness of the wound. Prof. Buchanan, of Glasgow, stated that he used carbolic acid, and laid much importance on free drainage. Mr. Schelkly, from America, at first used Listerism, but now used a combination of salicylic acid with iodoform or corrosive sublimate lotion with boric lint. Prof. Kœberlé, of Strasbourg, also spoke of the importance of preparing patients for operation, and said that no special antiseptic should be extolled at the expense of others. Prof. Trélat also spoke.

The general impression gained from this discussion was that each surgeon seemed to lay stress on his own method, and that with it he got good results.

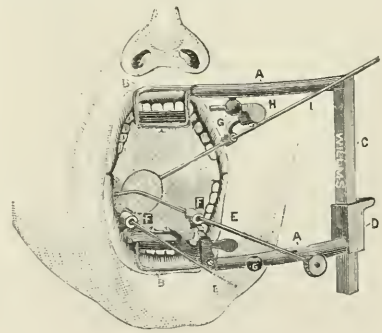
NEW INVENTIONS.

A NEW GAG, WITH TONGUE-DEPRESSOR AND MIRROR-ATTACHMENT.

By RUSSELL MURDOCH, M.D.,
of Baltimore, Md.

The gag is a counterpart of an eye-speculum described by me in the *Transactions* of the American Ophthalmological Society for 1883.

It has two blades (A A) with teeth-rests (B B). At the distal end of the upper blade there is, at right angles to



it, a rectangular bar (C). Similarly situated on the lower blade, is a sleeve (D) with square lumen. This sleeve fits closely over, and slides on the bar, and to effect this there is a convenient handle projecting from the side of the sleeve. The teeth of the patient lock the

instrument at any desired point, and consequently no set-screw or catch is needed.

The tongue-depressor (E) is made of No. 12 Stubbs's gauge wire. It is shaped like a long-armed capital letter U. A retaining button is screwed on one arm. When attached to the gag, the arms are encircled and slide through the two oscillating sleeves (F F), which ride upon the lower mouth-rest. These, together, maintain the horizontal plane of the depressor. A cog-wheel, attached to the right-hand sleeve, allows the surgeon to depress its point, but any return movement is prevented by a spring pawl.

The laryngoscopic attachment (H) consists of two elbows united by a universal joint. One has a sleeve which encircles the stem of a mirror (I), and through which it slides and rotates. The other elbow has a short rectangular arm, bevelled at its free end, and this fits in the socket of either of the raised buttons (G G) on the blades of the gag. The upper button supports the mirror in laryngoscopic, and the lower in rhinoscopic observations.

The chief claims of the gag for professional notice are the automatic character of the fixation by the teeth, and its greater promptness of removal from the mouth than any in use.

An attached tongue-depressor to a gag will, it is thought, commend itself as worthy of frequent trial in many throat operations. A suspended mirror, and also the addition of a palate retractor, suspended by an attachment similar to that of the laryngoscopic mirror to the other button on the gag, will give two free hands and a visible cavity while operating on a post-nasal growth.

Note.—These instruments have been made by the well-known firm of Wilms & Co., of Baltimore. They can be obtained of them singly or as a set.

NEWS ITEMS.

The New Hygienic Institute in Berlin.—Dr. Robert Koch has been appointed Director of the new Hygienic Institute attached to the University of Berlin.

The Royal College of Surgeons of England.—It is stated that as residuary legatee of the late Sir Erasmus Wilson, the Royal College of Surgeons of England will receive about £180,000.

Cholera Precautions in England.—Sir William Vernon Harcourt, the British Home Secretary, has issued a circular to the officials of English prisons, urging them to take extraordinary precautions for the purpose of keeping the prisoners in their charge clean and the prisons in the best possible sanitary condition, in view of the continued prevalence of cholera.

The Home Secretary has also issued an official notice to the factory inspectors, ordering them to give especial care to the sanitary condition of all places wherein large numbers of operatives are employed and to give every necessary sanitary instruction to the factory hands.

This action on the part of the Cabinet is accepted as an indication that the government are more alarmed now than they have been at any time since the outbreak of cholera in France, and that they possess information of the actual introduction into England of the seeds of the plague and entertain fears of a probable outbreak of the scourge.

Obituary Record.—Died at Narragansett Pier, on Sunday, August 31st, Riggin Buckler, M.D., of Baltimore, aged fifty-three years. Dr. Buckler was born in Baltimore November 4, 1831; he graduated in the Arts at Harvard University in 1851, and received his degree of M.D. from the University of Maryland in 1853. He visited Europe and remained there four years in hospital service. On returning to this country in 1857, he settled in Baltimore in general practice, and soon achieved prominence in his profession. He twice held the place of Surgeon-General of the State of Maryland.

NOTES AND QUERIES.

PERMANGANATE OF POTASSIUM.

To the Editor of The Medical News.

Sir: The *modus operandi* of permanganate as a deodorizer, that is, its immediate decomposition on contact with organic matter, is so frequently overlooked by prescribers as to seem to justify calling attention to this matter. For instance, in the last number of The News, page 184, an article appears, taken from a French journal, recommending that soles of cork, etc., be soaked in a solution of permanganate and dried, for use as pedal deodorizers. The permanganate would be decomposed at once on coming in contact with the organic material. The sprinkling of poultices with the solution is another mistake, for the same reason. Glycerine used in gargles, also, is equally destructive. Permanganate pills are now much in vogue for amenorrhœa; the salt can, with proper pharmaceutic skill, be put up in the pill form, an inorganic excipient being used, but the fact remains that it is decomposed on reaching the stomach, and any effect following the administration must be due to the manganese oxide.

Yours, T. D. Reed, M.D.

Montreal, August 20, 1884.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 26 TO SEPTEMBER 1, 1884.

Head, John F., *Colonel and Surgeon.*—Granted leave of absence for four months.—*S. O. 201, A. G. O.*, August 27, 1884.

Woodhull, A. A., *Major and Surgeon.*—Detailed as member of Medical Examining Board, at U. S. Military Academy, West Point, N. Y., vice Capt. R. H. White, relieved. Upon adjournment of the Board, to return to his proper station.—*S. O. 201, C. S., A. G. O.*

Bartholf, J. H., *Captain and Assistant Surgeon.*—Relieved from duty in the Department of the Columbia, and to report in person to the Commanding General, Department of Texas, for assignment to duty.—*S. O. 199, A. G. O.*, August 25, 1884.

Finley, J. A., *Captain and Assistant Surgeon.*—The leave of absence granted him in S. O. 91, C. S., Department of Texas, extended two months.—*S. O. 198, A. G. O.*, August 23, 1884.

Taylor, M. E., *Captain and Assistant Surgeon.*—Granted leave of absence for four months, to take effect on arrival of a medical officer at Davids' Island, N. Y., to replace him.—*S. O. 200, A. G. O.*, August 26, 1884.

Gibson, R. J., *First Lieutenant and Assistant Surgeon.*—Relieved from duty in Department of the Missouri, and to proceed to the Department of California for duty.—*S. O. 202, A. G. O.*, August 28, 1884.

Dietz, Wm. D., *First Lieutenant and Assistant Surgeon.*—Relieved from duty at the Military Academy, West Point, N. Y., and ordered to the Department of the Missouri for duty.—*S. O. 202, A. G. O.*, August 28, 1884.

APPOINTMENT.

McCaw, Walter D.—Appointed Assistant Surgeon, with rank of First Lieutenant, to date from August 20, 1884.

PROMOTION.

Lippincott, Henry.—Promoted Major and Surgeon, to rank from August 17, 1884, vice Woodward, deceased.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLV. SATURDAY, SEPTEMBER 13, 1884. No. 11

ORIGINAL ARTICLES.

TYPHO-MALARIAL FEVER.[1]

BY ROBERTS BARTHOLOW, M.D., LL.D.,

PROFESSOR OF THERAPEUTICS AND MATERIA MEDICA IN THE JEFFERSON MEDICAL COLLEGE, OF PHILADELPHIA.

IT happened to me to constitute one of a Board of Medical Officers, convened in Washington, in the summer of 1862, to propose a system of reports for the preparation of the medical history of the War of the Rebellion. In the nomenclature then submitted to the Department for adoption was the term *Typho-malarial Fever*. This name, suggested by Dr. J. J. Woodward, was accepted as describing a group of cases, then supposed to be of frequent occurrence, in which the morbid complexus of typhoid fever was modified by a malarial complication. The name, not the conception, was new. The circumstances of the time favored the reception and permanent acceptance of the new term. The nomenclature adopted by the Board was made official, and a large part of the medical profession of the United States, then in the army, were required to adopt it, and the term, which originally was intended as a convenient designation, came to be regarded as the exponent of a pathological condition.

Dr. Daniel Drake, that great medical genius of the West, fifty years ago, recognized the fact that typhoid fever, as was and is the case with many other diseases, received a certain impression from an existing malarial poisoning. The late Prof. Dickson and other observant clinicians, in all parts of the world within the malaria-breeding zone, have long been familiar with this fact. There can be little doubt, I think, that this view has been greatly exaggerated. The typhoid fever of Louis—typical typhoid—is capable of many modifications, of many variations under climatic and other conditions; but in what degree, soever, the clinical history may vary, the morbid anatomy does not vary. Those who study from books rather than at the bedside, are often quite unconscious of the remarkable variations to which the malady is subject, and hence are too apt to find in these departures from the typical, new forms. Dr. Drake saw typhoid as it marched with advancing civilization—as it developed with increasing population—and he fancied that it possessed new features. Dr. Woodward saw the typhoid of the Chickahominy, of an army of unseasoned men, exposed to unprecedented conditions, and he concluded that it was a new malady compounded of the typhoid and malarial disease. Even Drake saw that, in a limited sense, the typhoid poison is antagonistic of the malarial. Typhoid is the fever of old, of cultivated countries, and dense populations; malarial of new countries and sparse populations. As new countries are opened up to cultivation and to settlement, the original malarial diseases are replaced by typhoid. For a time, and, indeed, during the whole period of malaria production, the symptomatology of typhoid may be somewhat influenced by the prevailing malarial poison. I repeat, *may be*, for, as I shall presently show, typhoid is a *continued* fever, in a certain narrow and conventional sense, only.

The word *typho-malarial*, was made originally by Dr. J. J. Woodward to express his conception of a composite fever. The opinion as to its character entertained by Dr. Woodward has been expressed in his work on Camp Diseases (*Outlines of the Chief Camp Diseases of the United States Armies*, Philadelphia, 1863). On page 202, he says, referring to the morbid anatomy of Peyer's patches, "certain peculiarities cannot fail to strike the anatomist, which are often sufficiently distinctive to enable him to recognize typho-malarial fever by the post-mortem appearances alone." Again, on page 211, he styles it a "new hybrid"—in other words, a cross between typhoid and malarial fever.

Dr. Woodward admits that this view was not accepted by all the medical officers of the army (p. 210). In a paper read before the Medical Section of the International Medical Congress, in 1876, he could name but two opponents of his views—I quote his own words: "Dr. Roberts Bartholow, formerly an Assistant Surgeon in the Army and now a successful practitioner in Cincinnati;" the other "Dr. Jerome Cochran, of Mobile," formerly "a Surgeon in the Confederate Army." If there had been opinions or observations in contradiction of those expressed by Dr. Woodward, certainly only mine had been given formal utterance. My paper in opposition to the specific claim of Dr. Woodward, appeared in the medical volume issued by the United States Sanitary Commission soon after the close of the war. (*Memoirs of the United States Sanitary Commission*, New York, 1867.) In this paper, which appeared soon after Dr. Woodward's views had been published, I maintained that he was in error in supposing that the morbid anatomy of typhoid presented any peculiar features in consequence of a malarial complication. It was not until ten years afterwards, in 1876, that Dr. Woodward retracted the opinion he had at one time expressed, and then not through the official channel, but in a paper to which I have referred, which he read before the International Congress.

I maintained that as populations increase, typhoid supplants malarial fevers; that during the transition period a mixed fever prevails, a typhoid with a malarial complication, but that the morbid anatomy of typhoid remained always the same, and was not

[1] Read by invitation before the Medical Society of Berks County, and neighboring County Societies, in May last, at the City of Reading.

modified as claimed. Dr. Woodward, finally admitted this in the following language: "During my earlier studies I believed that I had observed certain peculiarities in the character of the ulcers in these cases, by which they might be distinguished from the lesions of simple typhoid. A larger experience . . . has convinced me that this opinion was premature. I renounce it as erroneous. There is really nothing in the lesions of Peyer's glands, in these cases, to distinguish them from ordinary cases of typhoid fever." (*Transactions of the International Medical Congress of Philadelphia*, p. 332.) On the next page to that from which I have just quoted, I find this question, and answer: "Is typho-malarial fever a special type of fever? and I reply, unhesitatingly, that it is not." We may then ask, if it is not a special type of fever, why give it a special designation? During the war a scorbutic taint, crowd-poisoning, overwork, affected the constitutions of men, and hence so far typhoid fever was modified by them. Should we not then have a special form of typhoid and a special name for such specimens of the malady? To such a *reductio ad absurdum* do we come by adopting this view.

In regard to the manner in which a malarial infection may modify typhoid fever, there is one source of erroneous observation, in an especial degree responsible for the prevailing misconception. That is—the thermal line of typhoid. Having the notion of a continued fever fixed in the mind, practitioners are too apt to forget that there are distinct remissions and exacerbations of the body heat in every case. There are diurnal variations corresponding to, but in greater relative proportion than the normal. In other words, typhoid fever is, properly speaking, a remittent fever. The likeness to the malarial remittent is all the greater, since in every fully developed case of typhoid, sweating is a pronounced symptom. The differentiation is the more difficult during the first week, since in some cases of typhoid there is constipation, and in some cases of remittent, diarrhœa. In the former, gurgling in the right iliac fossa may be wanting; in the latter, it may be present. A therapeutical means of differentiating, much relied on, may be misleading—I refer to the use of antipyretic doses of quinine—for a distinct reduction of temperature will be effected in both instances by the exhibition of massive quantities. I do not mean to infer, however, that the subsequent influence of the antipyretic will be the same in both diseases.

I fear that the misconception thus originating has vitiated the returns made to the Surgeon-General to such an extent as to render any conclusions drawn from them very misleading. This is the more to be regretted since the volumes containing the medical history of the War of the Rebellion, will have the authority of the Government.

Dr. Woodward, the author of the term typho-malarial fever, having abandoned the original claim as to its solidarity, it may be well now to try to indicate the real relation of the two elements composing the mixed fever.

First, as to the term typho-malarial. This is an unfortunate designation, for it implies the existence of a malarial fever into which the typhoid enters as an essential element. There is a total absence of proof that such a condition exists. Who has seen the morbid anatomy of malarial fever into which had been projected the changes peculiar to typhoid? It has already been shown that the changes characteristic of typhoid are in no respect modified by malarial poisoning. If then the typhoid poison or germ is received into an organism infected by the malarial poison, it undergoes development in accordance with its own laws. So completely does it dominate the situation that the action of the malarial poison ceases. The term *typho-malarial* is, therefore, a complete misnomer, a misleading phrase, which should be abolished from our nosology; and should no longer appear in our text-books.

Second, as to the supposed hybrid. I much doubt the existence of a typhoid fever, whose symptoms are modified by a malarial fever. Indeed, there are reasons for believing, that in a certain sense an antagonism exists between the two, so far, that in the presence of the typhoid poison, the malarial ceases to be active. I have already given a reason for the belief that the remittent character of typhoid has been a cause of error. At the beginning of the fever, and also during the last week, the remissions and exacerbations are so well marked as to be very confusing. I have always held that the thermal line of typhoid might receive an impression from a coexisting malarial complication,—might, therefore, become more distinctly remittent, but further experience has weakened this belief. If the morbid anatomy of typhoid is not thus affected, why the symptomatology? Examined anew in the light of a wider experience, I have been conducted to the conclusion that the modification in the thermal line, supposed to be due to a malarial complication, has, for the most part, no real existence.

The action of quinine in typhoid fever, and in pseudo typho-malarial. A further reason for believing in the entire autonomy and independence of typhoid is the failure of quinine to lessen the duration of the supposed hybrid, or to effect more than a transient reduction of temperature. It does not appear, indeed, that quinine acts in any respect differently on typho-malarial fever, than on typhoid. A massive dose effects a reduction of temperature, and in so far as lessened body heat mitigates the severity of the fever, quinine exerts a beneficial action; but that it cannot arrest the disease, or shorten its duration, is absolutely certain. Over and over again has the attempt been made, to cut short typho-malarial fever by heroical doses of quinine; over and over again has failure terminated these efforts.

I must here again point out how an error of diagnosis so often confuses the judgment of practitioners. I have already indicated how many cases of typhoid bear a superficial resemblance to remittent fever. The converse error is even more misleading. The more intense the malarial poison, the more nearly the resulting fever approaches the continued type. The order of form is well known; tertian, quotidian; remittent, of tertian, of quotidian type. If the poison be sufficiently intense, the quotidian remittent presents a thermal line closely approxi-

mating typhoid. Who has not heard of a remittent fever assuming the typhoid state?

I need not say to those here present that a "typhoid state" is far from the typhoid fever. If the nature of a remittent fever with quotidian remissions and exacerbations, is not understood, and sufficiently energetic doses of quinine administered to break it up, the typhoid state is presently assumed. This misunderstanding may readily occur if the history of the case is unknown and its development not watched from the beginning.

When I reported for duty at Fort Leavenworth, Kansas, in 1857, I saw for the first time those deadly malarial fevers which occur in the Missouri River bottom-lands. If such cases had fallen into my inexperienced hands, the most of them would have passed into the typhoid state. Fortunately for the patients and for my future usefulness, the Surgeon in charge of that great military hospital was Dr. John M. Cuyler, of the Army, a physician of great experience, familiar with the practice, then but little known, of massive doses of quinine. To my astonishment, his practice consisted in the administration of a single dose of thirty grains on the first day, twenty grains on the second, and fifteen grains on the third, by which time the fever had practically ended. He indulged in no preliminary skirmishing, no tentative experiments, but well-directed blows with doses that went to their object with unerring precision, were delivered.

Until recently I had supposed that these large doses of quinine, in the treatment of malarial fevers, had been introduced by our army surgeons, as claimed in Coolidge's Army Medical Reports of 1854. In Fenner's *Southern Hospital Reports*, there are several references to this practice in the Southern States. I owe to my friend Prof. W. T. Howard, M.D., of Baltimore, a reference to this practice of still earlier date. In the *Traité Anatomico-Pathologique des Fièvres Intermittent, Simple et Pernicieuses*, Paris, 1825, doses so large as forty grains are recommended in malarial diseases. For sixty years, therefore, it has been known that the severe forms of malarial fever tend to assume a low or typhoid state, unless energetically handled by heroic doses of quinine.

There still remains an answer to the question, What is the nature of the influence exerted by the malarial poison on typhoid fever?

For the reasons above given, it appears to be probable that when the typhoid germ begins its development in the body, the phenomena caused by malarial infection, if it exist, subside. I have held that the only modifications in the symptoms which occur, are the changes in the thermal line, the more pronounced exacerbations, and remissions, the greater excursions of the temperature. I am by no means sure that this opinion is correct. The source of error is so obvious, and mistake is so easily made, that it can hardly be doubted it often occurs.

If the malarial poison remains in abeyance during the predominance of the typhoid action, there comes a time when it asserts itself. After the typhoid infection has spent its force, there occurs an intermittent, which may greatly prolong the convalescence if not recognized and effectively treated. In my experience, this intermittent succeeds to the typhoid in all cases, in which a really active condition of the malarial poison exists. In the absence of such manifestation, we may well doubt that a malarial complication enters into the morbid complexus. Where the patient is simply affected by that which is styled "chronic malarial poisoning," the influence is insufficient to modify the typhoid process to an appreciable extent. If, however, the malarial infection is active, during the sway of the typhoid fever, it is either overpowered, or, at most, merely increases the daily thermometric range; but as the typhoid process subsides, then the malarial comes into play, and we have a convalescence interrupted or protracted by an intermittent or remittent fever. Often, indeed, have I witnessed these phenomena. I may now close my rather hasty observations, with a sentence from Woodward's paper read before the International Medical Congress at Philadelphia:

"And this brings me at length to answer the question—Is typho-malarial fever, a special type of fever?—and, I reply, unhesitatingly, that it is not." P. 333.

ON THE MALIGNANT METAMORPHOSIS OF DISEASED TISSUES.[1]

BY THEO. A. McGRAW, M.D.,
OF DETROIT, MICH.

THERE are inherent difficulties which make it impossible for even the most experienced surgeon to attain to a uniform success in the diagnosis of tumors. Swellings of the most diverse character frequently present exactly similar symptoms. Normal enlargements even may simulate those which are morbid, and it often happens that the practitioner has to wait for time to develop those differences which alone can make a diagnosis possible. These difficulties arise in a large measure, it is true, from the general likeness of all immature tissues, but there are, besides, others which spring from the tendency of one form of disease to develop into another, or, at any rate, to afford the stimulus which calls that other into being. Thus it has long been noticed that inflammatory and syphilitic deposits precede and perhaps cause the development of cancers and sarcomas, while benign growths not infrequently become malignant. The general practitioner, who necessarily deals but little with this class of diseases, in his anxiety to form a definite diagnosis is apt to forget that mature's boundaries are rarely definite, and that her outlines are often hazy. I propose in this paper to call attention to the practical bearing which these transitional forms of disease have in causing errors in diagnosis. My last winter's practice has indeed afforded an abundant supply of material with which to illustrate this phase of the subject.

Last summer, as I was about to leave Detroit on my vacation, a man thirty-three years of age consulted me about an indurated ulcer of the right side of the tongue, as large as a silver half dollar and in-

[1] Read before the Michigan State Medical Society, at its Annual Meeting, 1884.

volving the whole thickness of the organ. He had a syphilitic history of seven years' standing, and had had the affection of the tongue for one year. A competent surgeon at his home had, as I think correctly, diagnosticated the disease as syphilitic, and treated him accordingly. I could just feel on the right side of the neck over the carotid artery, a little swollen gland. I deferred all operative treatment until my return and put him on daily doses of iodide of potassium of forty grains, and had him apply iodide of potassium ointment to his neck.

On my return, three weeks afterwards, I found the tongue in the same condition, but the cervical glands had greatly increased in size. I operated soon after by splitting his tongue in half and removing the diseased portion, and then by dissecting the enlarged glands carefully away from the carotid and jugular sheaths, to which they had become attached. The patient rallied rapidly from the operation, and his tongue was soon well. Not so, however, his neck, for from it there grew a most malignant fungous mass, which in three months ended his life.

Now, here was a case, as it seemed to me, of the undoubted transformation of a syphilitic deposit into a cancerous tumor, and a good surgeon had failed to grasp the reality of the case from an unwillingness to credit a malignant tendency to a specific disease.

A similar case, which I treated for a short time over a year ago, occurred in the person of a married lady who came to my office with a most ugly looking ulcer of the tongue. After a cautious inquiry into the history of the case I concluded it was syphilitic, and put her upon large doses of iodide of potassium. I had in mind a system of treatment which, beginning with a strict antisyphilitic course of medicines, should be followed subsequently, if this failed, by thorough excision.

The ulcer indeed looked to me to have already become cancerous. She came, however, but once or twice, and when I heard of her again she was under treatment by Prof. McLean.

She had in the meantime gone to the Hot Springs, Arkansas, and there had been put on iodide of potassium at the rate of seventy-five grains a day. A temporary improvement followed this treatment, but it was only for a short time. Dr. McLean tells me that when she applied to him the case had become hopeless. The ulcer had eaten into the floor of the mouth, the surrounding tissues had become all molten together, and the neck was full of swollen glands.

She ultimately died of hemorrhage from the lingual artery which had become involved in the general destruction of tissue. In this case, also, I believe that an early and thorough excision would have saved a human life.

Soon after this experience, a poor fellow entered my office with a most undoubted sarcomatous growth of the right upper jaw. He was not yet thirty years of age and had had syphilis, but there could be no doubt that this was something more than syphilis. The jaw was greatly enlarged, the right nostril was closed with a fungous mass, the post-nasal spaces were blocked up with the growth, and the roof of the mouth depressed. It had progressed, in fact, beyond all possibility of an operation, and yet his physician from the wilds of the northern part of the lower peninsula, wrote to say that I must be mistaken in my diagnosis, as the man was undoubtedly syphilitic.

Whether the previous syphilitic affection in this case had any causal connection with the tumor I cannot positively say, but this seems to me certain, viz., that maglignant growths frequently spring from specific degenerations. Practical surgeons have to bear this fact in mind before shutting out a diagnosis of cancer on account of a previous syphilitic history.

I have had three cases of the transformation of tumors, apparently innocent, into highly malignant neoplasms. Two of these cases were moles which had been irritated by the application of caustics. Every surgeon is aware that moles are prone to malignant degeneration, and yet the actual occurrence of the change is sufficiently rare to make such cases worthy of record.

The first case was that of a fine, young man, not yet twenty-two years of age, who was sent to me by my friend, Dr. Small, of Saginaw. Some three months before a congenital mole had been irritated by his collar, and afterwards touched with caustic by a local surgeon. The resulting sore never healed, but became the seat of a rapidly growing melanotic fungus. This was finally excised, but when I saw him one month afterwards, it had recurred not only as a local growth, but also as a metastatic glandular affection. As a forlorn hope, I operated and removed as thoroughly as possible all apparent disease. The operation left a raw space as large as the palm of the hand in the back of the neck and a deep excavation in the subclavian triangle. The patient recovered without any difficulty from the operation, and in a few days was up and about. The operation was performed on Nov. 7, and so rapid was the recurrence that on Dec. 14, the patient, who had left the hospital, except for this cancer in good and robust general health, succumbed to the infection.

The second case was in the person of a man, twenty-six years old, whose home was in Imlay City. He was admitted to St. Mary's Hospital on January 3. Two years before a mole on the upper part of the right forearm had been irritated and finally destroyed with caustic. A year and a half afterwards, a tumor was observed on the lower part of his right arm, which was imperfectly extirpated by a local surgeon, after it had grown to the size of a hen's egg.

The wound never healed, and became the seat of a rapidly growing secondary tumor.

Some infected glands could be distinguished in the axilla, which in three days grew very perceptibly in size.

On Jan. 7, I amputated the right arm at the shoulder-joint, and removed a large mass of glands from the axilla.

This patient recovered and went home, but on May 20 returned with a new lump in the axilla, which I removed on the following day. He is now recovering from this latter operation, and anxiously debating whether he has yet escaped his enemy.

The first of the tumors proved to be a round-celled sarcoma. The second, a spindle-celled sarcoma. They may serve as a warning to such practitioners who recommend the destruction of moles

by mild caustics. I would not myself use any caustic whatever for a mole, preferring the safer method of excision, but he who uses a caustic for such purpose should choose one of the strongest, such as could destroy at one application not only the tumor, but also some of the underlying tissues. I am firmly convinced that not only in these cases, but also in cases of epitheliomata of the face, mild caustics, which reach only the superficial layer of cells, often do frightful damage. The lower strata, stimulated into activity, grow into the depths more rapidly than the caustic can penetrate, and a tumor, whose power for evil may have been but latent, suddenly develops a dreadful malignity. I do not mean, of course, to say that every irritated mole turns into a cancer, but who would take any chances when such possibilities lie before him?

Another patient, in whom I have this year had the sorrow to witness the transformation of apparently simple growths into highly malignant tumors, was a woman of some forty-one or forty-two years of age, whom I examined carefully two years ago for enlargement of both breasts. She had then noticed for several months growing tumors, which had attained, when I first saw her, to the size, in the right breast, of a hen's egg, in the left, of a large walnut. They seemed to be cystic, and, when I punctured them, I was able to collect about two ounces of a reddish-brown fluid. The microscope revealed in the fluid a few shrunken cells, some blood corpuscles, more or less altered, and granular matter. After the puncture, the walls of these cysts collapsed so completely that it was then difficult to find any abnormal swelling whatever. There were no perceptible indurations or nodosities. I came to the conclusion that the trouble was cystic and innocent, but requested the patient to call from time to time for examination. I saw no more of her for two years, until about six weeks ago she came to me again with both breasts the seat of extensive and unmistakable scirrhous cancer. The disease had reached an incurable stage, and my too favorable opinion had caused the loss of that golden time when a cure might have been possible. I have my own theory about those cysts of the breasts which occur in the persons of middle-aged women. They occupy dilated ducts, and may be classed with retention-cysts. Now, according to Cohnheim, there are two elements essential to malignancy. The first is the aggressive growth of certain groups of cells. The second is the loss of resisting power in the neighboring tissues. Cancer of the breast begins in the acini or the smallest lacteal ducts by the riotous proliferation of epithelium, but becomes cancer only when this epithelium has succeeded in forcing its way into the connective tissues immediately adjacent. If now this growth takes place, but the connective tissues sturdily resists its encroachment, the cell will eventually die and accumulate in the distended ducts. Their presence causes irritation, and the secretion of more or less fluid. Cysts form then which contain only such fluid and the débris of cells, and are apparently simple. At a later stage, however, the connective tissue becomes more atrophied with advancing age, and yields to the epithelial pressure. We have then the development of malignancy in growths which we had fondly believed innocent. I have been long suspicious of certain of these so-called retention-cysts, but have never until now had so marked an example of their dangerous tendency.

Of all complications, which are apt to mislead the surgeon in his judgment of abnormal swellings, the advent of tumor in inflamed and injured parts is the most deceptive.

By one of those curious coincidences which occur so often in practice, one physician was able to send me, almost together, two cases of sarcoma of the femur, in both of which a history of hurt and subsequent inflammation had deceived a most competent practitioner as to the true nature of the case.

Charles Coots, aged 24, had been in good health until last September. He was employed in a planing mill, and, while at work, sat at a table on which a wheel was turned by means of a leather band, which passed into the room below through an opening in the floor.

The constant draught of air through this opening, and the occasional rubbing of this band, caused an intermittent pain and soreness in his left knee. This became so severe that he was finally compelled to quit work and keep the house. He was treated for inflammation of the knee-joint for several months, and the fluctuations between apparent improvement and exacerbation of trouble seemed to establish the correctness of this diagnosis. On Jan. 10, 1884, he fell, and afterwards grew rapidly worse. It became evident that the case was one other than that of simple inflammation, and I was sent for in counsel. I advised amputation, and performed it at St. Mary's Hospital on Feb. 27, before the students of the Detroit Medical College. The patient was much reduced at this time, and I amputated between the middle and upper thirds of the thigh. I had reason soon to regret that I had not operated at the hip-joint, for a close examination of the stump showed numerous black points in the medulla of the bone, due to the presence of pigmented cells, although the soft parts seemed perfectly healthy. This demonstration of the greater speed with which the infection of tumors travels in the medullary cavity of bone than in the surrounding flesh was very instructive, as showing the folly of amputating in such cases through the bone. I believe that the rule ought to be universal, where the bone is involved, to disarticulate at the joint above. The patient was too weak for any further operative procedures, and he was left to recover from the operation with the certainty that subsequent amputation would become in time a necessity. The femur in this case was found to be the seat of an enormous melanotic sarcoma, which had involved the knee-joint, and almost entirely destroyed the lower part of the bone.

The second case of this kind occurred in the person of an old soldier, W. E. Lerrick, who had received a shell wound in the left knee during the late war, and had ever since suffered from lameness and stiffness of the joint. As the result, apparently, of a slight injury received about a year ago, the knee began to pain him again, and get hot and swollen. The diagnosis of inflammation was naturally made, and for

many months he was treated with various antiphlogistic measures. He was finally sent to St. Mary's Hospital, where he arrived on March 14, 1884. He had then an enormous tumor involving nearly the whole thigh, and ulcerated at the knee. No enlargement of the lymphatics could be detected. As a last resort, on March 17, I amputated at the hip-joint. The tumor proved to be a white round-celled sarcoma, and I was able to show by sections of the bone, as the trochanters, that the whole bone was involved in the disease. The patient is nearly recovered, and left for his home on June 10, a small sinus still leading into the cavity of the acetabulum. Now, in these two cases, I think that the most experienced surgeon would have been liable to mistake the nature of the trouble in the beginning, and every practitioner knows how difficult it is to escape from a prejudice when once it is formed. It has been said that any inflammation may prove infective, and I have had very many cases in my own practice in which cancer has seemed to graft itself upon inflammatory tissue. Whether the two which I have related were of this kind, or whether they were from the beginning cases of mistaken diagnosis, it would indeed be hard to decide.

I have just performed a palliative operation upon a woman for a large cauliflower growth of the uterus, which was discovered six months after childbirth. These cases are so common as to fall within the observation of every gynecologist of large practice, and are attributed by many to cervical rupture, the raw surfaces of which become irritated and covered with granulations, the cellular elements of which, instead of undergoing cicatrical contraction, multiply enormously, and acquire a property of infection. Whether this be so, or whether they spring from some minute placental remains or from residual fœtal cells, this much is true, that such growths follow close upon processes, which, if not altogether normal, would nevertheless have an entirely different result in by far the large majority of cases. It is by no means the only class of cases in which granulation-tissue is the starting-point of cancer, but it will serve here to good purpose as an example, because such tumors are often overlooked in the early part of their history, their peculiar symptoms being masked by those sequelæ of childbirth which cause sometimes for months morbid discharge from the uterus and vagina.

As regards the diagnosis of these cases, in which morbid tumors are suspected of forming in otherwise diseased tissues, I must confess that I know of no criterion by which we can render ourselves sure of our diagnosis in the early and transitional stages. The microscopic examination of a few detached cells gives but an uncertain and doubtful result. The examination of any large mass of tissue can be done only by an exploratory operation, which to most patients would seem as formidable as the radical operation, and we need to satisfy ourselves of the diagnosis before urging the patient to such severe measures. I have frightened some patients away even by proposing an exploratory puncture with a small needle. The fact is, time is the great solver of many of these diagnostic riddles, and if surgeons only guard themselves against those prejudices which fix themselves in the mind after a false diagnosis has once been formed, errors in opinion may often be rectified in time to operate efficiently and thoroughly. Ulcers which are persistent in places where ordinary ulcers ought to heal, syphilitic sores which resist the appropriate treatment, cysts which refuse to heal after the evacuation of their contents and destruction of their lining membranes, uteri which continue to discharge blood and debris an undue time after delivery, all ought to awaken suspicion, and incite the practitioner to the most thorough examination. If then the cause remains doubtful, the patient ought to be given the benefit of the doubt, and those severe and radical measures used which would be applied in cases of pronounced cancer.

DIRECT APPLICATION OF THE GALVANIC CURRENT IN SALPINGITIS.

BY HORATIO R. BIGELOW, M.D.,
OF WASHINGTON, D. C.

I WISH to call attention to what may be considered a unique case in gynecological therapeutics. It is not sufficient of itself to establish any definite principle, although it may lead up to such investigation as shall place this procedure upon a logical basis.

I have had under observation for many months a case of oöphoritis and salpingitis that made but slow progress under the systematic treatment of electricity, massage, Turkish baths, and graded muscular exercise, that I always resort to in these conditions. The usual symptoms were well marked —objective and subjective. The sound passed easily and for quite a distance up the right tube. Menstruation was irregular, painful, scant, and altered in character. It was perhaps a suitable subject for Tait's operation, but we cannot all hope for the brilliant results of that eminent surgeon, and I have already expressed my views upon oöphorectomy, as well as upon the general management of oöphoritis.

I had previously seen excellent results from the galvanic current; one electrode (negative) being pushed well up into the vagina, while the other was applied externally over the location of the ovary. It seemed to me that an insulated electrode of the size of the ordinary uterine sound, might easily be carried into the tube, quite as easily, indeed, as the sound itself, and that the negative current might alter the entire catarrhal condition of the membrane, setting up a new action—a reparative one—within the tube itself, and that this influence might be transmitted well up to the ovary. At all events, it was an experiment worth trying. I knew from an extended use of electricity in the diseases of women, that both currents were well tolerated by the sexual apparatus; indeed, the uterus is only slightly susceptible, less so than any other part of the body.

I had made an electrode of the same dimensions as my uterine sound—insulated—and terminating in a bulbous metal expansion. This was carried without the least difficulty well up into the tube and was made negative. The positive electrode was

pressed over the external parietes in the location of the ovary. I began with a current strength of five milliampères, continuing the application for three minutes. The positive electrode was small, and pressed firmly down. The patient made no complaint; on the contrary, she confessed to a feeling of satisfaction at the sense of warmth. I made applications twice a week, varying the strength of the current, but never beyond twelve milliampéres. She always felt better after each séance, and now, after three months of this treatment, is really radically better. She has little or no pain; the menstrual function is accomplished quite naturally, and the enlargement of the tube is constantly growing smaller, so that it is now impossible to admit the sound.

May it not be possible that we have here such a powerful alterative remedy, as will relegate to cystic and well advanced degenerative changes only, the necessity of the surgical operation?

HOSPITAL NOTES.

CINCINNATI HOSPITAL.

Service of N. P. DANDRIDGE, M.D.

(Reported by W. H. WILDER, M.D.)

EXTRACTION OF A BULLET FROM THE URETHRA; TWO CASES OF EXTERNAL PERINEAL URETHROTOMY.

FRANK STARK, colored, groom, aged twenty-six, well developed, was admitted to the Cincinnati Hospital December 17, 1883. Says he contracted syphilis four years ago, and gonorrhœa, for the first time, eighteen months ago—recovering from the latter trouble rapidly. He remembered that on a certain day, about one year previous to his admission, he suddenly found himself unable to micturate, and consulted a physician, who introduced a catheter and also prescribed certain medicines, from which, he says, he derived no relief.

Since that date he has been unable to void his urine in a full stream, but it escapes from him in drops, and any attempt at micturition is accompanied by severe pain. When admitted, the bladder was distended, and the patient complained of some pain and uneasiness.

An unsuccessful attempt to introduce a small rubber catheter having been made, he was ordered a hot hip-bath, gr. x pulv. ipecac. comp., and rest in bed.

The next morning, Dec. 18, he was feeling much better, having passed urine more easily than before. The urine was alkaline, and contained an abundant deposit of phosphates, and very tenacious viscid mucus, with some pus.

Dec. 19.—He said that the obstruction appeared very suddenly, and that the day before he first noticed it he had been able to pass a good-sized stream. On introducing a sound, a hard body was struck, about four and a half inches from the meatus urethræ, which gave the click of a stone when touched by the steel. This foreign body could be felt as an irregularly shaped point of induration, at the peno-scrotal angle.

20th.—Dr. Dandridge attempted to extract the foreign body with forceps, but it was so firmly held that it was necessary to make an incision along the median raphé at the junction of the penis and scrotum down to the point of a sound which had been introduced into the urethra, and which was pressing upon the point of obstruction. A leaden bullet, about $\frac{42}{100}$ inch calibre, considerably flattened and indented, nearly covered with urinary salts, and firmly embedded in the tissue of the urethra, was removed with some difficulty. After the operation, a No. 16 English sound was easily passed into the bladder; the wound was dusted with pulv. iodoform, and the patient ordered to remain quietly in bed.

In the evening of the same day, the pulse was 96, temperature 100½°, and the patient very cheerful. At that time he related an incident which threw light upon the presence of the bullet in the urethra. In 1870, he received a pistol shot in the left groin, and although careful search was made for the ball by several surgeons, it was never found. A small circular cicatrix, about one inch below the middle of Poupart's ligament of the left side, indicated the point of entrance of the missile; and several scars, about an inch in length, on the inner and posterior surfaces of the thigh were evidences of fruitless exploratory incisions for extracting the same.

26th.—Pulse 72, temperature 99°. Complained of some pain in scrotum, which was slightly swollen. A suspensory bandage was ordered, and the iodoform dressing continued. Patient was instructed to micturate in the knee-elbow posture, at the same time raising the scrotum from behind, to prevent as far as possible any gravitation of the urine into the tissues of the scrotum.

31st.—No. 14 English sound was passed into the bladder. Patient was improving rapidly. This sound, No. 14, was passed daily until the date of his departure. When discharged, on January 19, 1884, the wound had nearly closed. Micturition took place entirely through the penis, and the patient was feeling well.

Remarks.—I can find no case on record in which a missile of any kind having entered the bladder, has subsequently become impacted in the urethra. In the *Medical and Surgical History of the War of the Rebellion*, Part II., surg. vol., there is a record of twenty-one cases of vesical calculi consequent upon shot wounds of the bladder. Thirteen of these calculi had developed around a missile, such as a bullet or fragment of a shell, this acting as a nucleus; and small fragments of bone, cloth, or hair had constituted the nuclei around which the other eight had formed. None of these entered the urethra, probably on account of the large size of the bullets or fragments; and all were removed by lithotomy operations. There are on record five cases of individuals who received gunshot or pistol-shot wounds of the bladder who subsequently passed the bullet through the urethra. Three of these cases are quite ancient, having been cited by Elscholtz, in 1693; Thomas Bartolinus, in 1680; and Mangther, about 1721. The other two were reported, in 1855, by Dr. C. D. Stickney (*Boston Med. and Surg. Journ.*), and, in 1867, by Assistant Surgeon J. V. Lauderdale (surgical volume of the *Medical and Surgical History of the War of the Rebellion*). In these cases, the balls were small enough to escape through the urethra during a forced attempt at micturition. The passage of small fragments of bone by the urethra after gunshot injuries of the pelvis and bladder was much more common in the late war; and in one case, some bone-fragments, which had become impacted in the

deep portion of the urethra, were extracted by Dr. Thomas G. Morton by perineal section.

In the case of Stark, the obstruction had evidently existed for over a year, with severe vesical tenesmus and painful micturition; but how long the foreign body had been impacted in the position where it lay could not be determined.

Its jagged surface had caused it to become firmly embedded in the mucous membrane, and the irregular surfaces left space for the urine to trickle past the obstruction.

After introducing the sound, the thought of the presence of an impacted vesical calculus was entertained, and an attempt was made to crush and remove it with forceps; but, this failing, removal of the foreign body through an incision became necessary.

It seems evident, in this case, that the bladder was not perforated originally by the shot, for no manifestations of vesical trouble appeared prior to a date about one year before his admission to the hospital, but that it subsequently entered by a process of ulcerative absorption, having probably worked its way through the loose connective tissue of the pelvis to a position alongside the bladder-wall.

Had there been made a proper examination when he first complained of vesical symptoms, the discovery of the foreign body would have followed, and a lithotomy operation would have accomplished his relief. Although a linear incision through the corpus cavernosum into the urethra is not likely to cause a constriction of that canal after the wound has healed, yet, in this case, we can reasonably apprehend a form of traumatic stricture, owing to the lacerated condition of the urethra, caused by the pressure of the jagged body.

MEDICAL PROGRESS.

The Treatment of Strictures of the Œsophagus.—Professor J. Hjort, of Christiania, read a paper on this subject at the International Medical Congress at Copenhagen, in which he concluded that:

1. In cases of cicatricial stricture of the œsophagus—even in its upper part—impermeable to instruments, gastrostomy *en deux temps* is indicated; and then to treat the stricture, through the fistula, by means of electrolysis, as has been successfully done in one case.

2. It is also probable that the treatment by electrolysis should replace internal œsophagotomy in cases of cicatricial stricture, still possible for a small sound.

Phosphated Peptones in Obstinate Vomiting of Pregnancy.—Dr. A. Judet calls attention to the necessity of administering phosphate of lime in pregnancy and during lactation. This is particularly indicated when the father or mother has a scrofulous diathesis. By its action it is an element which meets the drain upon the osseous system of the mother; and being an excitant of nutrition it causes assimilation of the albuminoids, thus fortifying, in a measure, the organism and placing the mother in the best conditions for furnishing without fatigue the proteic elements necessary for the development of the fœtus.

He reports the case of a woman, twenty-seven years of age, who was having attacks of uncontrollable vomiting, being in the third month of utero-gestation. Chloral and valerianate of caffeine gave only temporary relief. Phosphated peptone in an infusion of bitter orange-peel was then given, six teaspoonfuls of the former being given during the day. After slight symptoms of intolerance, this was well retained and the proportion was gradually increased to twelve teaspoonfuls a day, this being the only food taken. This exclusive regime was kept up for five days, after which she began to take small quantities of other food. The peptone was continued in doses of two to four teaspoonfuls a day not only during pregnancy, but during the whole time of lactation. Digestion, which after all former pregnancies had been painful, was now performed in a normal manner. In previous pregnancies she had been unable to nurse her children, but she nursed this child during the full period, and its dentition was much earlier than that of any of the others.

It should be remarked that there are differences in phosphate of lime, and it should be carefully selected, and furthermore it is assimilated with ease by the system only when combined with a nutrient proteic substance. Peptone and phosphate of lime make a very rational and *physiological* preparation for building up the osseous and muscular systems.—*Gazette Hebdom.*, August 8, 1884.

Two Cases of Myomotomy.—E. Bidder reports (*St. Petersburgher med. Wochenschr.*, 1884, N. F. Jahrg. I., No. 1) two cases in which he has performed this operation. The first case, in which laparotomy was performed by Schröder's method, easily recovered. In the second case, there was a tumor of the posterior cervical wall, which reached over an inch above the symphysis. The body of the uterus, of normal size, was on the anterior portion of the tumor. The tumor was removed *per vaginam*. After slitting the anterior lip of the cervix, a wedge-shaped piece was removed from the tumor, the base of which formed the posterior lip. The vagina was then packed with iodoform-gauze. During the course of the next week, the tumor sank into the vagina, and became partially freed from its capsule, filling the vagina as completely as would a child's head. On the twelfth day, it was removed with the fingers. An hour after the removal, tolerably free hemorrhage set in, which was controlled by a tampon. Recovery took place quickly, and without fever.

The tumor was six inches long, and a little over three inches wide, and about the size of a child's head. From the ease with which this tumor was enucleated, Bidder advises that these tumors be removed through the vagina whenever possible.—*Centralbl. f. Chirurgie*, August 2, 1884.

Extirpation of the Uterus Through the Vagina.—Dr. E. Kufferath, of the University of Brussels, reports, with a general consideration of the subject of extirpation of the uterus, the case of a woman, forty-five years of age, from whom he removed the uterus by the vaginal method. The disease was of two years' duration. The wound was completely cicatrized six weeks after the operation, and the patient seemed perfectly well for four months and a half, when infiltration again appeared.—*Annales de Gynéc.*, July, 1884.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, SEPTEMBER 13, 1884.

ARSENIC IN MALIGNANT LYMPHOMA.

THE treatment of malignant lymphoma or lymphadenoma, which should not be confounded with sarcoma of the lymphatic glands, is most disappointing, as the disease almost invariably continues to progress until death ensues from sheer exhaustion. Now and then a cure follows extirpation or the parenchymatous injection of tincture of iodine, hyperosmic acid, or Fowler's solution; but the local and internal administration of arsenic, which was brought prominently into notice by Winiwarter, in 1875, and is so much vaunted by many surgeons, has afforded so little satisfaction that it is rarely resorted to out of Germany.

Attention has again been called to the arsenical treatment of this class of morbid growths by KAREWSKI, in a paper read before the Berliner Medicinische Gesellschaft, and published in the *Berliner klinische Wochenschrift*, Nos. 17 and 18, 1884. Of the four cases, three are recorded as cured, and one as improved, there having been freedom from recurrence for four years in one, and twenty-nine months in two. In the first, the pharynx, and the cervical and axillary glands were affected; in the second, the tonsils and the glands of the neck, axillæ, and groins were the seats of the disease; while, in the third, in addition to the tumors designated in the second case, the liver and spleen were greatly enlarged, and the patient was suffering from diffuse bronchial catarrh. In the first and third cases, the remedy was employed hypodermatically and by the stomach, and in the second, by the stomach alone. After a few injections the tumors began to diminish in size, and the diminution went on so rapidly that in from six to eight weeks glands of the volume of a hen's egg were reduced to that of a cherry. Not only was this good result witnessed in the tumors injected, but also in distant growths, the tonsils resisting the influence of the remedy longer than the other glands.

In the discussion which followed the reading of the paper, ten additional cases were reported by Güterbock, Küster, Heymann, and Grunmach, which tend to demonstrate that the prognosis of malignant lymphoma, when subjected to the arsenical method of treatment, is not so bad as it is usually regarded. There can be no doubt that in the fourteen cases life was prolonged, but whether a final cure resulted is quite another question. In three of the fourteen there was recurrence of the disease, and the reports would have been far more conclusive had the time that had elapsed after the so-called cure been recorded. As we have seen, the patients of Karewski remained well, *with a persistent slight enlargement of the affected glands*, for three years, on an average; but, as examples of recurrence after two years and more have been recorded by Winiwarter, Zesas, and others, not a a single one of the cases here noticed can be said to be safe from recurrence.

Our own experience with the disease indicates that there is no tumor which recurs so surely after extirpation, or the arsenical treatment, or which is so surely fatal, as the one under consideration. Hence, we are disposed to accept these cases not as cures, but merely as prolongations of life. From the influence exerted by arsenic upon the primary and recurrent growths, we are of the opinion that malignant lymphomata should, when practicable, be excised, and recurrence be guarded against by the administration of Fowler's solution by the mouth.

THE ETIOLOGY OF INFLUENZA.

NOTHING in medicine has more completely set at naught the vaunted investigating power of man than the cause of influenza. Its very name, now adopted by common consent out of a host equally vain, originally denoted its supposed mysterious nature, and the uselessness of scientific effort to find out by searching its cause. The elders turned to the elements, earth, air, fire, and water, without result. They were, perforce, content with the theory of some occult "influence" from the stars. In later days, when the nature of influenza and the manner of its epidemic spread came to be well known, the mystery of its cause still remained wholly unsolved. Even recent epidemics, studied under the most favorable conditions for research, have shed no light upon its actual cause.

It has been easy to show, from time to time, what it is not, and to overturn high castles of theory that

stood upon no base of fact. But the spoiling of the grapes went on, and the little foxes were not found. Then opinion came to drift miasmward. What is miasm? In this instance it was something that accumulated in the northeast, beyond Tartary, and was puffed by Boreas, when there was enough of it, across China, Russia, all Europe, and the high seas to the New World, and sometimes around again to far Cathay. Certainly, these vast pandemics were a puzzle. Whatever the cause of them, it could only be transmitted by the most general of media—the atmosphere. Its devastations were like those of the locust, but the field upon which it feasted was the wide, wide world. Surely it bred as it journeyed; else it would have been dispersed to the four winds of heaven in traversing areas neither bounded by continents nor limited by seas. Moreover, colonies of the miasm found abiding places and were left behind; and thus local outbreaks took place from time to time, after the great pandemics were ended. Hence, men came to think and speak of this miasm of influenza as something organized—living, and to explain it by the germ theory of disease.

Happier in his suggestion of the truth than in his versification was the poet who wrote:

> "So, naturalists observe, a flea
> Has smaller fleas that on him prey;
> And these have smaller still to bite 'em,
> And so proceed *ad infinitum*."

And this particular flea, like the celebrated tormentor of the Irishman, eluded capture. When you put your finger on him, he wasn't there. There has now, however, arisen in Würzburg an investigator who has succeeded where all who came before had failed. Otto Seifert is his name. With his sling and a pebble from the brook he has brought down the giant whom the rest went out against in vain. And the manner of it was as follows: Dr. Otto Seifert had the opportunity of observing an epidemic of influenza in Würzburg. It was not exactly a pandemic. The first case came under his notice, in the Julius Hospital, on the 14th of January, 1883, and the last on the 24th of March, in the same year; and they numbered, in all, *seven*. He was, therefore, enabled to cope single-handed with the whole epidemic. He not only routed it, horse and foot, but he also took it captive, and has studied its appearance and habits with the care and interest due to so distinguished a prisoner of war. As the reader anticipates, it is a coccus, and a micrococcus at that. Enlarged 350 times, its length is from 1.5 μ to 2 μ, and its breadth 1 μ; and its number in the sputum is legion. It arranges itself mostly in long chains, the rank and file, less often in pairs (diplococci), and occasionally it stands forth alone (monococcus). It was caught in the secretions of the nares, and in the sputum, in the earlier actions of the campaign. Later, when these became fouled and purulent, the coccus forsook them. In the tears, even when they most bedimmed the eyes, it was not found. This captive was clad by its conqueror in a robe of methyl-violet, and made a magnificent appearance.

In order to establish its identity, laborious comparisons, of the nature of control-experiments, were made. Examinations of the same secretions of many other sick than the seven were conducted, but with a negative result. The coccus was not there; nor was it found in any blood—even of the seven. The inoculation of two white guinea-pigs failed. Like other fierce captives, it grew sullen, and refused to do its trick. Or was it like those noble beasts which become sterile in captivity? Dr. Otto Seifert magnanimously gave it a new robe, of almost Tyrian purple, but the spirit of the victor prevailed, and he has called it by a name not its own—"Influenzacoccus," and has broken its spirit by likening it to the base coccus of gonorrhœa.

A full, true, and particular history of this discovery will be found in Volkmann's *Klinische Vorträge*, No. 240, 1884.

ACUTE INFECTIVE OSTEOMYELITIS.

IN the *Fortschritte der Medicin*, Nos. 7 and 8, 1884, may be found an interesting paper on the part played by micrococci in acute osteomyelitis, from the pen of KRAUSE, of Halle, whose researches confirm those of Struck, made in the laboratory of the Imperial Board of Health of Berlin, under the direction of Koch. The pus with which the investigations were made, and which was obtained from nine cases of osteomyelitis in man, disclosed, after careful culture, the usual orange-colored micrococci, and, in addition to these organisms, in one case, a white coccus, which had previously been described by Rosenbach as occurring in three examples of closed osteomyelitic abscesses, and to which he gave the name staphylococcus pyogenicus albus.

In the experiments made upon eighteen dogs and seven guinea-pigs, with a view to reproduce the disease by inoculation, the culture-fluid was mixed with two parts of water. Small quantities, whether introduced under the skin or into the peritoneal cavity, were followed by negative results, and the intraperitoneal injection of a larger quantity merely set up peritonitis, without any indications of lesions of the bones. When, however, the bones were broken, an abscess frequently formed at the point of fracture. Thus, of fifteen cases, suppuration ensued in seven after a single injection, while in three others several injections produced a local abscess in the vicinity of the fracture, as well as in the neck of the femur in one. In three, in addition to the abscess at the site of the fracture, there was extensive suppuration of the me-

dulla. In all, the pus, as well as the cultures, contained the characteristic micrococci.

The intravenous injection of putrid matter was resorted to in four dogs, in which one of the bones of the extremities had been broken. Abscesses formed in every case at the seat of the injury, but without extensive suppuration of the medulla; and the organisms present in the pus were entirely different from those found in the pus of osteomyelitic abscess.

The results of his experiments lead Krause to the belief that the lesion produced at the site of a fracture in the lower animals by the inoculation of the cocci of osteomyelitis is not the same as osteomyelitis of man; and that the cocci of acute infective osteomyelitis of the human subject are merely possessed of extraordinary pathogenic and pyogenic properties.

A SUPERANNUATED OPINION.

Budin says the opinion that the fœtus is nourished by the amniotic liquor is singular and superannuated, and is unworthy of discussion. Charpentier states that the theory which regards this fluid as nutritive, and that the fœtus swallows and digests it, has now sunk into an oblivion from which it can never escape. But, how little prophets know, for the theory has escaped from oblivion and appears in *The American Journal of Obstetrics* as a new-born child, not as an exhumed corpse! Among the arguments adduced in its support we fail to find the one which Hippocrates used, to prove that the child sucked while in the womb, for, said he, if it did not suck then, how would it know how to suck when it was born? so, if the child did not swallow liquor amnii in the uterus, how could it swallow milk at birth?

Certain proved facts militate against the new-old theory, and a few may be mentioned. The size of the child is usually in inverse proportion to the quantity of amniotic liquor; according to the theory, the more of the liquor the greater ought to be the size of the child. It is hardly probable that a fluid which often, if not always, contains products of retrograde metamorphosis is designed for food. Acephalous monsters are often well developed, but they have not been able to drink a drop of this asserted sole nutritive material for the fœtus. Experiments upon the young of inferior animals have shown that a diet exclusively of amniotic liquor means starvation.

It has been shown by Wiener in a recent number of the *Archiv für Gynäkologie*, that in the latter part of fœtal life the function of many organs can be exercised just as after birth, and especially that the great development of the follicular apparatus of the mucous membrane of the stomach and intestines enables them to perform digestion, but as these organs usually contain excrementitious matter, their activity is not important. It does not seem to us that an argument for the exclusive nourishment of the fœtus by the swallowing and digestion of liquor amnii can rest on the condition of the digestive apparatus, any more than we can assert that the special senses of sight and hearing are exercised before birth, because the organs of these functions are sufficiently developed for action.

PSEUDARTHROSIS OF THE TIBIA.

An ingenious method to restore the usefulness of the limb in pseudarthrosis of the tibia, following great loss of substance in complicated fractures, is described by Hahn in the *Centralblatt für Chirurgie*, May 24, 1884. The conical extremity of the upper end of the tibia having been removed, the fibula is divided at the same level, its lower extremity implanted in the medullary canal of the tibia, and the lower end of the tibia refreshed in an oblique direction, in order to strengthen laterally the support afforded by the fibula. The plan was successfully carried out by its deviser in a case in which the defect between the extremities of the tibia measured three inches and two-fifths.

POLLUTION OF THE SCHUYLKILL RIVER.

The efforts which have been made to protect the Schuylkill River from pollution from sources within the limits of Philadelphia have been only in part successful. By the acquisition of Fairmount Park many nuisances on both banks of the river, which contributed toward the contamination of the water, have been abated. But there still remain numerous and well-known sources of sewage contamination of the most repulsive and dangerous character, which, at certain seasons of the year, and in certain conditions of the stream, have caused the water to be exceedingly unwholesome. Notwithstanding these facts, and in the face of the protest of citizens, every effort made to have the evil removed has been a failure.

Several years ago when legal proceedings had been commenced against certain mill-owners for discharging deleterious substances into the river, City Councils ordered the suits to be discontinued, for the reason, as surmised, that interference with industrial establishments would have the effect of driving them beyond the city limits. Whatever may have been the motive which induced this unwise action, the result has been to perpetuate a nuisance which has been increasing in magnitude year by year until at last it has become imperative that the rights and health of the people should be protected.

Upon evidence collected by the Chief Engineer of the Water Department, the City Solicitor has been directed to prosecute the offending parties, and, with

the support of the Board of Health, this officer has commenced proceedings against a number of persons who have been bound over to answer at court for creating and maintaining a nuisance injurious to the public health.

These proceedings will be watched by the community with the most intense interest. The hope is that they may be successful for their direct results, and also in establishing a precedent which shall serve as a guide in similar cases. If not successful, the burden of providing an outlet for sewage, other than the river, will rest on the city, and the final consummation of this object be hastened. In either event the people will have gained an important advantage.

We congratulate Jefferson College, and the medical profession of this city, on the election of Dr. Mallet, to succeed the late Prof. Robert E. Rogers. No abler man has held the Chair of Chemistry since the College was founded, and not one who combined more of the requisites for this important position.

Dr. Mallet received his first medical and scientific training at the University of Göttingen, where he graduated Ph.D. Devoting himself to chemistry and cognate subjects, he has achieved a position in the front rank of those devoted to this department of science. He is now a Fellow of the Chemical Society of Great Britain, and also of the Royal Society, the latter the highest and most prized scientific distinction attainable in England, or, indeed, in the world. Dr. Mallet is M.D. of the University of Louisiana, and LL.D. of the College of William and Mary, Virginia. Besides these titles, he is fellow and member of various scientific bodies at home and abroad. He now resigns the Chair of Chemistry in the University of Virginia, to accept the same position in the Jefferson Medical College of Philadelphia.

Dr. Mallet is a fluent and agreeable lecturer, and is a great favorite with students, because he combines an agreeable manner, a lucid style, and a penetrating voice. He is now fifty-two years of age, in the maturity of his powers, and many years of his best working capacity are yet before him. We do not doubt that in his new position he will add much to the reputation of the chair which he fills, and of the city to which he is about to remove.

At the recent meeting of the Canada Medical Association Dr. William Osler was elected President for the ensuing year. This honor we learn, from the *Canadian Practitioner*, was tendered at this time, in view of Dr. Osler's probable early transfer to a new field of labor in the States, and with singular unanimity, as a special mark of the esteem in which Dr. Osler is held by his professional associates in the Dominion.

SPECIAL ARTICLE.

THE CHOLERA CONFERENCE AT BERLIN.

(Concluded from page 248.)

Prof. Virchow opened the adjourned discussion upon Dr. Koch's address by saying that, in his opinion, the Conference had been called as a jury to which Dr. Koch should speak, and it was for those present to say whether they were satisfied with his report. In order that the discussion should be kept within bounds, certain questions had been prepared, which covered all the points raised by Dr. Koch's address, and upon which they were requested to express their views.

The first question considered was:

Is cholera generated by a specific infectious material which comes from India only?

Dr. Koch said that he had thought it necessary to bring up this question because it has been doubted on many sides, and especially of late, whether cholera is a specific disease, and originates only in India.

Prof. Virchow believed that there could scarcely be a discussion on this question in Germany; at least he did not know that any noteworthy attack upon the truth of this proposition had been made in Germany in the last decade. No dissenting opinion was expressed.

Is the infectious material contained in the stools, and eventually in the vomited matters, or is it also found in the blood, urine, perspiration, and expired air?

Prof. Virchow said that this question was important because the members of the French Commission in Egypt believed that the infectious material was found in other parts of the body, as in the blood, which was denied by Koch.

Dr. Koch said that, so far as he had seen, the infectious material was found only in the stools, with the exception of one time in the vomited matters. It cannot be contained in the blood, as is shown by the fact that infection never occurs from making an autopsy, whilst with other diseases, as splenic and relapsing fever, in which the infectious material is found in the blood, infection does occur.

Is the presence of the comma-bacillus of diagnostic value (a); and is the infectious material of cholera identical with the comma-bacillus (b)?

Dr. Koch thought that both these points should be considered together, and that (*b*) covers both. He wished, however, to state expressly that the microscope is sufficient only in a few cases; and that it is especially necessary that culture-methods be employed.

Prof. Virchow said that the practical question is still subordinate. He would state the question (*b*) thus: Is the infectious material of cholera to be considered as identical with the comma-bacillus? And he would say that some of the elements of certainty were still lacking. On the one hand, cholera has not been communicated to animals through the medium of the comma-bacillus. This, however, is not an absolute counter-proof. Many experiments have been made with the view of communicating cholera to animals. Nor is the necessity of a successful experiment of this kind removed. The experiments of Vincent Richards are well known, but it seems probable, according to Koch, that the disease which he caused was a kind of

intoxication by septic or poisonous material produced by the bacilli. It is certain that in investigations of this kind that comparative experiments should be made on the one hand with pure cultures from the infected animal, and with cholera dejecta on the other. Nor does it yet appear to be absolutely impossible to produce a case of cholera in an animal.

On the other hand, he has expressed himself from the first, that he thinks it very probable that the problem, which has remained in suspense for ten years, as to the existence of a specific microörganism, has now been definitely solved; and further, that of the many microörganisms which are found in the cholera dejecta there is no other one which with any probability can be accused of specificity. Certainly the whole history of cholera, its manner of spreading, shows that that it must be referred to a living organism; and all measures for its prevention must be based on the supposition of this living organism. Since, also, it is entirely improbable that cholera is spread by the transportation of any chemical substance; and since, on the other hand, out of the entire sum of the organisms which are found in cholera only one appears to be in any way peculiar to it, it must be apparent that the probability is extraordinarily great that this one is the peculiar organism of the disease. Koch has reported that in certain dejecta, as also in certain specimens of the intestines of cholera patients, almost pure cultures of this bacillus exist; and that in the soiled linen also, which we recognize as a dangerous means for the transportation of the disease, the growth of these bacilli was very rapid and powerful. From this it seems conclusive that, in a measure at least, the doors are closed against further hypotheses. As to whether this bacillus is present in any other disease or under other circumstances, we cannot yet definitely determine.

DR. KOCH, in referring to the experiments of Richards, recalled the fact that his results could be considered as nothing else than an intoxication. The hogs died in an incredibly short time; in two and a half hours at most. Furthermore, Richards has not succeeded in reproducing his infectious material. He would not assert that there is no animal which could not be affected by the infectious material; he only says that in all those animals which have hitherto been experimented on, and which come in contact with cholera patients, not one has become choleraic. The question, therefore, is still unsettled. But Richards's experiments prove nothing whatever against the signification of the comma-bacilli; on the contrary, they appear corroborative of his opinion as to the etiology of cholera, because one learns in this way that a toxic substance is formed in the intestinal contents under the influence of the comma-bacilli.

PROF. VIRCHOW said that as regards the question, whether the demonstration of the comma-bacillus is of diagnostic value, we know that Dr. Koch is not entirely certain that the diagnosis is assured by simple microscopical proof of the bacillus. We may now ask: If a doubtful case occurs in which the symptomatology points to Asiatic cholera, and microscopic examination should show, without further experimentation, that numberless bacilli were contained in the discharges, would Dr. Koch be doubtful as to the real nature of the case?

DR. KOCH said that in this case he would not be in doubt for a moment. But it does not often occur that one finds large quantities of the comma-bacilli in a microscopical examination, made with the view of establishing the diagnosis; and, as a rule, culture-experiments are necessary, and should never be omitted. He returned, therefore, to the question as to the practical value of the demonstration of the comma-bacilli; he did not consider it a matter of indifference whether, for example, in the very first cases, which have perhaps been introduced by a ship, or in some such manner, to ascertain certainly whether they are cases of true cholera or not. Prof. Hirsch has said that the difficulty may be avoided by waiting, in order to see whether the cases recover, in which event they are cases of cholera nostras; but men may recover from Asiatic cholera also; and we must wait further and see if the cases spread, in which event the most favorable moment for meeting the disease has passed. Under all circumstances, it is very important that the first cases be taken in hand, and rendered harmless by proper regulations. The diagnosis of the first cases is of great consequence, not only on the very first introduction of cholera into Europe, but also on the appearance of cholera in any place, since then we may render the first cases harmless by isolation.

As regards the difficulty of the methods for recognizing the comma-bacilli, he believed that the coloring of the tubercle-bacilli, which was very quickly adopted, is more difficult than the culture of the comma-bacilli; and furthermore, as very many physicians have successfully colored the tubercle-bacilli, these experiments can certainly be performed by the majority, if not by all, of the health-officers.

DR. SCHUBERT asked in what stage, that is, how soon the comma-bacilli are found; and whether they can be found in the dejecta at the very beginning of the disease?

DR. KOCH stated that he had shown that they were found at the very beginning of the disease. In reply to a question by Prof. Hirsch as to whether, in the case of a man coming to Berlin with the symptoms of cholera, but in whose intestinal discharges no bacilli could be found, he would keep him under observation, Dr. Koch said that he would regard such a man as suspicious. With regard to the necessity of sending cholera material to a special place to be examined, Dr. Koch said that he hoped that it would not be long before every physician would be able to make such examinations for himself.

In reply to Dr. Fränkel, Dr. Koch said that the difficulty of making these examinations was greatly overrated; it is very easy to get the proper kind of gelatine now, and one has only to warm the gelatine, mix it with a particle of mucus from the dejecta, and put it on a glass plate. The plate is then put under a bell-glass, or between two common plates, as he had done in Calcutta. An especial warming apparatus for the culture is not necessary; a summer temperature in the room is entirely sufficient.

Does the infectious material possess great capacity for resistance, and a permanent condition? Is it destroyed in a short time by drying?

PROF. VIRCHOW referred to a late discussion which he had had with Prof. von Pettenkofer on this subject, in which the latter had gone so far as to state the possibility of the material remaining in a permanent form for

a long time, so that the germ of the infection may remain latent in a place for many months and then cause an outbreak of the disease; and he regarded it as very possible that the germ had been introduced into Toulon early in the year.

DR. KOCH said, in reply, that his experience went to show that the cholera germ possessed neither a capacity for resistance nor for remaining in a permanent form. It has been reported that an epidemic of cholera has been caused in a certain part of Switzerland from the sending of rags from Zurich, but the whole matter is so superficially reported that it is entirely uncertain whether all other sources of infection were excluded, that no value can be attached to the case. Certainly, we can refer to endless cases in which rags, soiled with cholera discharges, have been sent out from infected places and no case of cholera resulted. In reply to certain statements of Prof. Hirsch, that there had been intervals of several days or weeks between the first case of cholera and the outbreak of the epidemic in a place, he said that this had no bearing on what he intended by the expression "permanent condition" (Dauerzustand). He now has material from splenic fever which has been dry for twelve years and is still active. We have examples in which syphilis has been inoculated after one year or longer; and we know that vaccine virus remains active for several years. This is what he meant by "permanent condition." But soiled linen cannot remain moist for even a few weeks. He has kept the comma-bacilli in a reagent-glass for six weeks, but they did not on that account possess a permanent form. As soon as they were dried they died immediately. It is noteworthy that on trading vessels, which carry all sorts of articles which could contain the infecting material of cholera, cholera never breaks out except during the first few days after leaving port. But on large vessels it is otherwise; the outbreak may occur soon after leaving port, or it may not occur for two, three, or four weeks, or longer. Now it is strange that the infecting material should remain in a permanent condition only on those ships which have a number of men on board, and get active by degrees. How is it that this never occurs on trading vessels, or those which have only a few men on board, who are not so thickly packed together? This, in his opinion, is one of the most striking examples to show that as a rule the infecting material dies extraordinarily quickly, and that it is only maintained in men by a continuous contagion; which is certainly rendered possible in these extraordinary circumstances by the living together of so many men. The statements which have been frequently made as to the transportation of the disease by the clothes of travellers are therefore very uncertain.

PROF. HIRSCH thought it very possible that in a place in which cholera has become epidemic, the bacillus may be maintained in a moist material when circumstances are unfavorable for its reproduction, and be reproduced again when the circumstances become favorable, and so create a new epidemic; and he referred to the two epidemics in Dantzig in 1848–49.

DR. KOCH replied that this could not be understood as a permanent condition, such as we understand it in other bacteria. It really raises an entirely new question, which should not be confounded with the expression "permanent form," but which is worthy of consideration. He has shown that the comma-bacillus can stand a very low temperature, and that it can exist apart from the human body—on potatoes, for example—or its existence may be prolonged for some time in a reagent-glass with gelatine, or on linen. It is possible therefore that some such thing as this occurred, and that the comma-bacillus underwent a slow growth under restricting circumstances, or held its own for a time without finding an opportunity for infecting. This is always possible, though he has had no such experience, and cannot speak with certainty. To determine this, one must go to a place from which cholera has disappeared for some time, and thoroughly examine all places in which the infectious material could possibly be retained. This could not be done in Calcutta because it is never free from cholera.

Can the infectious material get into the body in any other way than through the digestive canal?

DR. KOCH said that he had purposely introduced this question into the discussion because Pettenkofer is of the opinion that it can also be introduced by the breath and through the lungs.

PROF. VIRCHOW remarked that von Pettenkofer rejects every other method of infection than that by the air and the lungs.

DR. KOCH said that he had found that, under exceptional circumstances, the infecting material can be conveyed through the air, but only to a very short distance; and it may be said, as a rule, that it is not thus introduced. The example to which he referred was noticed in Alexandria, where the sewers discharge into the new harbor; the sea-water was thus soiled in the vicinity, and when standing at the water's edge, one was obliged to clean his eye-glasses about every five minutes when the breakers were high, as they were covered with spray. It is very easily imagined that such spray, from water containing cholera discharges, may carry the infecting germs, and it is the more probable from the fact that a number of the people living on the new harbor were attacked by cholera.

PROF. LEYDEN referred to the fact that the persons who carry cholera corpses are often infected, and said that although they might possibly be infected in some other way than through the air, he thought this hypothesis the more probable; not that the material necessarily reaches the interior of the body through the lungs, but it may be conveyed to the mouth through the air.

DR. SKRZECZKA thought it also possible that in dry weather the infecting material might be carried through the air in the dust, and thus reach the mouth; and that it was also possible that this material may be first dried so that it can be carried about by the wind.

DR. KOCH said that it would be very strange if only the men employed in handling the bodies should be infected, and the nurses and the physicians who come into closer relations with the cholera patients, and with the vaporized discharges, should so often escape. In reply to Prof. Leyden's remark that many of the nurses were attacked, and died, in the epidemic in Dantzig, in 1866, he said that it frequently happens that nurses and physicians are not much more often attacked than other people; they are accustomed to wash and keep themselves clean, but they could not take precautions against the dust. The men who attend to the bodies, however, are

in especial danger, as they go into the dead-house and eat there. But they are not alone exposed to the dust-form of the infecting material, but can be infected in many other ways. To the remark of Prof. Leyden, that he did not mean that the dust was the carrier of the germs, but that he could see no difficulty in supposing that the germs of the infectious material might be suspended in the atmosphere if a strong evaporation was going on, Dr. Koch replied that he must oppose this altogether. All experience with infecting materials and microörganisms is opposed to such a theory.

Is the infectious material reproduced in man, or does this occur independently of the human body in the soil, and is man (and animals) only the carrier?

PROF. VIRCHOW said that there was another question which would come in here. If this is essentially an air-breathing organism, is the human intestine an especially favorable place for its development?

DR. KOCH said that he had already asked himself the same question. But there must be a supply of free oxygen in the intestine, or at least such a combination as will furnish oxygen to the bacillus. We see the bacilli living in great numbers in the intestine, and we see also that if the air is removed from the body they cease to grow. From this it seems that they must find oxygen in some way. It may also be stated that there were large numbers of other bacteria in the intestine, which also stopped growing under the same circumstances. And the oïdium lactis, which needs oxygen for its development, sometimes grows very richly in the intestine.

PROF. VIRCHOW said that he considered the question as to the soil more important, whether the infecting material is reproduced in the soil, and whether man serves only as the carrier. He thought it very probable that it was reproduced both in the soil and in man. As regards the soil, Dr. Koch has at least shown the possibility that moist earth may serve as a base for its growth.

Is a direct transportation possible, or must the infectious material go through a kind of ripening or growth in the soil or elsewhere?

PROF. VIRCHOW thought that on this point nothing further could be said than what had already been stated; namely, that there is no ground for holding to a hypothesis of a special generation-change or ripening. Certainly, after what had been said, such an assumption would be somewhat arbitrary.

DR. KOCH said that this assumption relates not only to the soil, but also maintains that the infecting material would need a special process of ripening in soiled linen, since the linen cannot be infectious in the fresh state. But the assumption has been especially supported by the experiments of Thiersch, and he was glad to hear it discussed. He himself believes that the soiled clothing is infectious as soon as it becomes soiled.

Is the infectious material conveyed only by human intercourse?

What are the carriers of the infectious material to distant places; ships, articles of clothing, letters, healthy or infected men?

What are the carriers of the infectious material to neighboring places; cholera corpses, cholera effects, soiled clothing, articles of food, water (for drinking and household purposes), the air, insects?

DR. SKRZECZKA said, in reference to these questions, that from Koch's standpoint it did not seem impossible that the contagion could be conveyed by rags and clothing. And it has been certainly proved that by drying for a certain length of time the development of the bacillus and its capacity for spreading are checked. It is, however, not entirely certain what is to be understood by this drying. It is well known that rags are often piled in large heaps, and it seems that a considerable time would be required in order to dry the whole heap.

PROF. VIRCHOW said that rags are no more important as elements for carrying infection than filth; and if, for example, the rags and soiled clothes of a poor man who has died of cholera be thrown into a heap of rags, the possibility of infection is just as great as though the whole heap was composed of soiled rags.

DR. KOCH would only say that he had had no practical experience as to the question now under consideration, and it seemed very doubtful to him. The question of the possibility of infection by means of rags was considered in the Cholera Congresses at Vienna and Constantinople, and no one could bring forward a single example of cholera being spread from rags, as, for example, amongst the rag-sorters in paper mills; and it must be concluded that the handling and working of the rags is such that the infectious material is destroyed. And of what avail would it be to keep rags out of the country while men infected with cholera are allowed to come in? The possibility of the transportation of the infection by rags is, in the light of experience, infinitely small, whilst that by apparently healthy men is very great. In answer to a question by Prof. Virchow, he said that in his experience the comma-bacillus dies quite soon in clear water, that is, within a few days.

Is a special individual predisposition necessary for the infectious material to become active?

How long is the stage of incubation?

Does recovery from cholera confer immunity from the disease for any definite period?

Can the action of the bacilli be regarded as a kind of intoxication?

PROF. LEYDEN said that one attack of cholera seemed to give a certain immunity against a second; but that this immunity is not absolute. Persons have been known to have three attacks of cholera in one epidemic, but it is seldom that a person is twice attacked in two epidemics separated by a short interval of time.

DR. KOCH, in answer to a question by Prof. Hirsch, said that he had found out nothing further regarding the period of incubation than had already been stated in his report.

PROF. HIRSCH said that he had never known of a period of incubation of less than two days, and that, as a rule, it was from three to four days—never five—as he learned in 1873 on his cholera expedition.

PROF. VON BERGMANN said that it seemed important to him that, for the prophylactic measures which must be employed, we should be able to make use of Dr. Koch's experience as to the spread and destruction of the infectious material. To the answer of Dr. Koch, that this would involve, what they wished to avoid, a determinate judgment as to the entire conception of cholera, and that each one should form his own opinion from what had been said in the discussion, Prof. von

Bergmann replied that each one could do this, but it was important to protect commerce and the community. As to what had been said, it gives a good deal of latitude to the physician. As regards the experiments on drying, he would propose that certain disinfection regulations be tried beside those which have been already used. All possible materials should be tried, and disinfection with different antiseptics and in different places.

Prof. Virchow then announced that the discussion was closed, and said that he had some hope that they would meet at another time in order to hear of new experiments, and to discuss other points. That would of course depend upon the course of events and especial circumstances. He then expressed his thanks to the members of the Imperial Health Office, and especially to Dr. Koch, who had not only welcomed the visitors, but had imparted so much new and important knowledge to them.

Cholera Nostras and the Comma-bacillus.—The *Deutsche medicinische Wochenschrift*, of August 21st, states that during the past few days there have been a number of cases of cholera nostras in Hamburg, which ran a rapid course. Careful microscopical examinations were made of specimens from the last fatal case, and culture-experiments were also made, with the view of finding the comma-bacilli, but with completely negative results.

REVIEWS.

The Hip and its Diseases. By V. P. Gibney, A.M., M.D., Professor of Orthopædic Surgery in the New York Polyclinic, etc. 8vo. pp. iv. 412. New York: Bermingham & Co., 1884.

The author of this book has had unusual opportunities for the study of joint-affections, having for thirteen years resided in the Hospital for the Ruptured and Crippled, in New York, during which time he has seen over two thousand cases of hip-joint disease alone—an astonishing number to come under the observation of one man. It need hardly be said that conclusions deduced from the study of so large a material are worthy of the utmost consideration; and although our space will not permit a critical analysis of them, we will mention a few of the most important.

In the first place, we note the author's statement that the majority of cases of hip-joint disease occur before the eighth year, and are the consequence of an ostitis interna, the focus of the disease being in or near the centres of ossification; that the head and neck of the femur are oftener involved than the acetabulum; that synovitis is secondary to the ostitis, and is simple if developed by contiguity, and purulent if by perforation; while after the age of eight years the origin of the disease is a central ostitis, a periostitis, a chondritis, or a synovitis, with about equal frequency.

In regard to the etiology of joint-disease, the author's experience leads him to divide the cases about equally between those in which the disease depends upon an inherited strumous diathesis, and one in which this has been acquired. One of these, however, he regards as the great predisposing cause of all chronic inflammatory bone lesions of the hip. He thinks the disease may be excited by a traumatism, exposure to cold, acute disease—an exanthema, for example, and most frequently—while in many cases no exciting cause can be discovered. He has about equally little faith in the way in which an exciting cause is often decided upon, and the way in which an inherited diathesis is decided against.

In regard to the matter of treatment, Dr. Gibney favors a method which is somewhat eclectic. The expectant method—that is, the symptomatic, if it may be so expressed—he thinks will secure good results in very few cases; in the large majority it is utterly inadequate to arrest the disease or secure the best result. For this reason it is to be rejected whenever the diagnosis of chronic ostitis of the hip is certain; when there is doubt, it may be adopted till the case becomes clear. The so-called physiological method of Dr. Hutchison—the crutch and high shoe—he thinks a delusion, securing only temporary improvement; though it has a certain value as part of the expectant plan of treatment. His preference is decidedly for fixation-apparatus; extension he does not seem to have much faith in. Short splints, which permit motion, are of little use, in his opinion. The long splint secures the best results in competent hands. The only basis for the proper treatment of hip-joint disease, he holds to be the idea that this is not a synovitis, but a disease of the bone-substance, requiring the same principles for its management as a fracture, namely, fixation and rest.

As a whole, it may be said that this book is worthy of most careful study. It has some defects of style, and is opposed to the convictions of some who think better of certain methods of treatment than the author does. But it is full of suggestions, and exhibits a thoroughly candid, though fearless, spirit in dealing with matters of dispute. In fact, its excellences are so many that justice cannot here be done to them all, and its defects so few that it would be hypercritical to dwell upon them.

SOCIETY PROCEEDINGS.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Eighth Annual Meeting, held at Highland Falls, N. Y., August 27, 28, and 29, 1884.

(Specially reported for The Medical News.)

(Concluded from page 271.)

August 28th, Second Day—Morning Session.

Dr. L. A. Duhring read a paper on

DERMATITIS HERPETIFORMIS AND ITS RELATIONS TO IMPETIGO HERPETIFORMIS,

in which, after describing the disease and its several varieties, he endeavored to show that the disease of Hebra was merely one manifestation of an extensive multiform and protean process. The history of impetigo herpetiformis was referred to, and a *résumé* of all the reported cases given, the conclusion being arrived at that the so-called impetigo herpetiformis of Hebra should be viewed as the pustular variety of dermatitis herpetiformis.

DR. FOX thought great credit was due Dr. Duhring for taking so comprehensive a view of many varying forms of disease which had hitherto been described under so many different names, as pemphigus pruriginosus, herpes chronicus, herpes gestationis, etc. He thought that all these belonged to the disease which Dr. Duhring had described.

DR. J. C. WHITE was convinced that the more we studied these cases the more difficult would we find it to classify them absolutely. He was inclined to think that the term multiform dermatitis would apply to them better than the others which had been suggested. He was not quite ready to admit that the writer of the paper had shown the existence of an absolute connection between his own cases and those which Hebra described as impetigo herpetiformis. He had never seen a case of Hebra's fatal impetigo of pregnant women, and would therefore prefer to regard the question of the identity of the two affections as still undecided. He saw no more reason for regarding the affection described by Duhring as of a neurotic origin than in almost any other inflammatory affection of the skin. Pigmentation was rare in the cases that he himself had seen, and the affection did not recur. He called attention to the fact that the disease was much more likely to be confounded by the general practitioner with eczema than with herpes.

DR. W. A. HARDAWAY thought that a certain class of cases in which the lesion assumed the form of vesicles, papules, and pustules could properly bear the term "herpetiform." He thanked Dr. Duhring for grouping these and giving them a perfectly satisfactory name. He thought there was a neurotic basis to many of these affections, but he would not regard it as a disease any more than he would call a drug eruption a distinct disease.

DR. A. R. ROBINSON spoke of three cases which he regarded as belonging to the class described. He felt that thanks were due Dr. Duhring for classifying these cases, which all dermatologists had seen and were at a loss to designate. He also was not willing to admit, without further investigation, that they were identical with Hebra's cases of impetigo herpetiformis. He had never seen the scarring described by Dr. Fox as occurring in the disease.

DR. S. SHERWELL said that he believed Hebra's cases to have been of a septic origin, identical with those often seen in military hospitals infected with hospital gangrene. He himself had seen many such in the ambulance at Sédan under the care of Sir Wm. MacCormac. He was inclined to suggest the name of "dermatitis necrogenica" for such cases, believing that even in Hebra's cases in pregnant and puerperal women, there might have been a septic absorption from an occluded tube in salpingitis, from the peritoneal cavity, a uterine clot, retained placenta, etc. The pruritus so common in the cases he was induced to regard as the result of the irritation from the deposits in the skin.

DR. DUHRING, in closing the discussion, said that his paper was practically a synopsis of one read at the last meeting of the American Medical Association, which was not yet in print. His information concerning the disease was based upon the careful study of sixteen or seventeen cases of the affection observed during the past fourteen or fifteen years. He did not regard the objections raised against the term "herpetiformis" as valid, there being at first in many of the cases a distinctly herpetic character. He admitted that most of his cases were of a different type from those of Hebra, but some of them closely resembled the latter, except that they did not prove fatal. A few of them were so acute as to present cutaneous disturbances of the most intense grade. He thought the difference between the two sets of cases simply one of degree. He thought that most of his cases had a neurotic origin. In some cases the disease is undoubtedly septicæmic, as it doubtless was in Hebra's cases. The causes of the disease were various. In some of his cases the affection was both neurotic and septicæmic, and he would soon report a case in which the disease was caused by a nervous shock, it having appeared on the next day. In his experience pigmentation was common, some of the cases resembling mulattoes. The disease was unquestionably a distinct affection, as much as any skin disease. He thought the term "necrogenica" decidedly objectionable, as in many cases there was not a possible suspicion of a septic origin.

AUGUST 29TH, THIRD DAY—MORNING SESSION.

In the absence of Dr. Henry W. Stelwagon, the Secretary read two papers forwarded by him entitled: *A Case of Late Cutaneous Syphilis (Acne-form Syphiloderm of the Nose), Illustrating the Occasional Necessity of Large Doses of Potassium Iodide;* and *A Case of Vitiligo Involving the Whole Surface.*

DR. W. A. HARDAWAY then read a paper on

A CASE OF GENERAL IDIOPATHIC ATROPHY OF THE SKIN.

The patient was a blind man, aged twenty-three years, of healthy parentage, and having a sister who was also blind and, he said, suffered from the same skin disease as himself. His trouble dated from infancy, and he had had eye-trouble for sixteen years. With the exception of headaches, his health was good. His intelligence was good, but he was poorly nourished. His face presented a rosaceous appearance, the skin being thickened. No papules or pustules were present. There were scars around the mouth, and his lips were thickened. The skin of the neck was pigmented in spots, and red on the sides, showing enlarged vessels. Front of trunk presented a shining, checkered aspect, due to many pigmented spots of various sizes and atrophic macules. The whole skin, in fact, was atrophied and tense. There was a number of cicatrices over the chest and abdomen, and the umbilicus was on a level with the surrounding skin. The back presented the same aspect as the front of the body. No telangiectases were at any time visible. The skin around the elbows was deeply pigmented and slightly scaly. The skin and muscles of the hand were atrophied, and the sides of the fingers were adherent to each other as far as half way up to their tips. The condition of the lower limbs resembled that of the upper. The feet were about normal. The hairs were short and scanty all over the body. The perspiratory function was poorly performed, but the cutaneous sensibility was not much altered. There were no marks of subjective symptoms. Examination of the eyes showed necrosis of the conjunctivæ, adhesion of the lids to the globes, and opacities of the corneæ.

DR. L. A. DUHRING said that his study of the recorded cases of this disease had taught him that beyond atrophy there were no special features which distinguished the process, neither telangiectasis nor pigmentation being essential elements. In the scleroderma of Hebra and the angioma pigmentosum et atrophicum of Taylor the features presented often varied greatly. We meet with cases of the disease in all grades, from those having no tendency to degeneration to those developing sarcoma or carcinoma, as in the graver forms of the affection.

DR. R. W. TAYLOR gave it as his opinion that the condition of the skin in the case reported was not like that met with in angioma pigmentosum et atrophicum, this patient presenting simply an ill-nourished, senile-like condition of the integument, with no evidence of vascular disturbance. The process had not been active enough to lead to neoplastic formations. In cases showing these, they usually appeared at the junction of skin and mucous membranes, or upon surfaces constantly exposed to irritation or friction from active motion.

DR. J. C. WHITE was unable to agree with Dr. Duhring as to the affinity which he believed to exist between the different varieties of atrophic processes in the skin. In one class of cases we met with loss of pigment and a deposition of epithelium, without change in the corium, and in another hypertrophy of the corium was a marked feature. In still another class of cases, new growths, such as sarcoma and carcinoma, were present. He did not think that the case reported could be connected with these. In the majority of the cases he had alluded to, the atrophy was a mere phenomenon, and not the essential feature of the disease.

DR. A. R. ROBINSON then read a paper on

MILIARIA AND SUDAMINA.

His object was to attempt to define clearly the true nature of the affections, and the conclusions he had reached were largely based upon careful microscopical studies of the diseases. Section through the deep-seated vesicles (which usually occurred on the face) showed that the papular or vesicular formation consisted of an exudation into the rete mucosum around the orifice of a sweat-duct; composed of serum, corpuscles, and more or less sweat, but never of the latter fluid alone. The changes in the rete were similar to those encountered in eczema, and the exudation came from the vessels of the papillæ. A catarrhal condition of the sweat-glands was also often noticed. He concluded that miliaria alba and rubra were not inflammatory processes of the sweat-glands, but rather of the skin around them. Specimens of sudamina had revealed the fact that the vesicles were always formed in the corneal layer, and that they were in direct communication with sweat-ducts. The surrounding rete mucosum was normal, and the contents of the vesicles were therefore sweat. The glands and ducts seemed normal. The disease was therefore not an exudative process, but consisted in an increase in the sweat-formation from hyperæmia with some obstruction to the escape of the sweat; he therefore concluded that miliaria alba and rubra were forms of eczema, or catarrhal inflammation of the skin, due to heat, irritating clothing, acrid sweat, etc. That the affection should not be called sudamina was shown by the fact that the contents of the vesicles were not sweat, but of a serous nature. The dew-drop like eruption was not an exudative affection, but a disturbance of the sweat-glands, the result of an hyperidrosis. He thought that the term miliaria should be dropped, as the affection was of an eczematous nature, and that the term sudamina should be applied to it.

DR. W. A. HARDAWAY objected to the use of the term eczematous as applied to the affection under consideration, as the latter was a true dermatitis and eczema was a distinct disease.

DR. J. N. HYDE was inclined to accept fully the views advanced in the paper. He thought that miliaria and lichen tropicus were simply due to accidents occurring in the course of an eczema.

DR. J. C. WHITE thought that any attempt to lessen the confusion in dermatological nomenclature should be warmly welcomed; and also that the position taken by the author was the only philosophical one. He himself recognized no such diseases as miliaria alba and miliaria rubra as distinct affections, but regarded them as merely forms of eczema. The question was, after all, one of definition only.

DR. L. A. DUHRING held that miliaria was a disease characterized by true inflammatory phenomena, such as papules, vesicles, and vesico-pustules, beginning around the sweat-glands and ducts. It seemed to him very plausible that the products of this inflammation should show themselves at some distance from the glands, and not at their orifices. He had always held that the disease was primarily caused by some disturbance of the sweat apparatus, resulting in vesiculation or papulation or diffuse hyperæmia of the general surface.

DR. ROBINSON called attention to the fact that the sweat-glands stop at the upper part of the corium, there being no perspiratory apparatus in the epidermis. In the so-called miliaria the formation of papules or vesicles takes place around the sweat-orifices, which proved that the disease was not an affection of the glands. The point of greatest hyperæmia is around the orifices of the ducts, and if this should be prolonged a quasi-inflammatory process would result, while if the irritation were not too prolonged or intense, vesicles or papules would be formed around the congested spot as a *pars minoris resistentiæ*, as it were, without the sweat-glands themselves being in the slightest degree involved. Hyperidrosis alone never gave miliaria without the influence of some external irritation. He thought that as we had dropped the old term for this affection, lichen simplex, we might just as advantageously drop miliaria.

DR. R. W. TAYLOR then read a paper on

A PECULIAR RINGED AFFECTION OF THE GLANS AND PREPUCE.

He described three cases of the affection seen during the past ten years. The patients were all from forty to fifty years of age, and all free from syphilis. Marked neurotic disturbances preceded and attended the outbreak in all the cases, in one an attack of creti-epididymitis and recurring attacks or balano-posthitis, and in another a chancroid had been severely cauterized on the glans, which led to long-continued swelling and other inflammatory disturbances. In all the cases the disease appeared in the form of a few rings covered with thin, firmly adherent, glistening scales, seated upon a normal mucous membrane without hyperæmic halo.

The lesions always began as a ring, and not as a papule spreading peripherically. After the lesions had appeared they remained stationary, showing no tendency to extend, and no new ones coming out. The affection was confined to the mucous membrane, the adjacent skin not being involved in any of the cases. Disagreeable sensations in the affected and adjacent parts were present in all of them, and the author of the paper had recognized the existence of a marked neurotic element in all. The affection resisted obstinately all local treatment, and would grow better and worse in a very capricious manner. The cases all finally recovered under the long-continued use of large doses of arsenic. The first case has since remained free from the disease for six years, the second five. He was loath to regard the disease as one *sui generis*, but in studying the cases he had carefully eliminated syphilis, tinea circinata, and psoriasis from the diagnosis.

DR. L. A. DUHRING said that, as far as the gross appearances of it went, he was very familiar with the diseases described. As regards the subjective symptoms, they were absent in his cases. These were also three in number. He was very much puzzled when he first saw them, but had finally concluded to call them lupus erythematosus. After listening to the paper, he felt satisfied that the cases were instances of the same affection Dr. Taylor so graphically described. In his cases the appearances, the course and evolution of the lesions, the occasional outbursts of hyperæmia, and the persistence of delicate very superficial cicatricial tissue here and there after the disappearance of the congestion, all pointed to lupus erythematosus. The course of the disease was very variable, the rings at times shortening from central pin-head-sized papules, and increasing to one-half inch in diameter, often coalescing and clearing up in the centre and scaling off. At times the lesions took the form of patches, not rings. They were seated upon the glans, extending over the corona and spreading over the mucous membrane, half on the corona and half on the prepuce, being most marked on the former. These cases were free from neurotic manifestations, and all proved very obstinate. A cure was finally accomplished in two of them by destroying the lesions with caustic potash.

DR. J. C. WHITE had had one case under observation for some months. The glans alone was involved, over almost its entire surface. The disease had existed a year, and was no better when last seen. He had made no positive diagnosis, but thought that it might have been lupus erythematosus.

DR. W. A. HARDAWAY described what he regarded as a similar case. The patient had been treated for psoriasis and recovered. A few months later he presented himself with a red, scaly, not thickened nor elevated patch on the side of the glans penis. No improvement had occurred after six months' treatment, even with increasing doses of arsenic. The course of the affection was entirely unlike that of psoriasis.

DR. W. T. ALEXANDER, of New York, then suggested that perhaps the affection might partake of the nature of the disease known as leukoplakia buccalis. He thought there was a marked resemblance between the clinical histories of the two affections.

DR. E. WIGGLESWORTH, of Boston, cited the case of a man whom he had successfully treated for leukoplakia buccalis, and who afterwards returned with a kidney-shaped patch, clearing up in centre, on the glans penis. It was attended with disagreeable itching sensations. There were no evidences of syphilis in the case, and he had eliminated from the diagnosis everything but lupus erythematosus, an instance of which affection he finally pronounced it. It finally disappeared under the use of pure carbolic acid.

DR. TAYLOR, in closing the discussion, said that in his cases the affection did not begin as a papule, but always as a ring, clearly defined, as large as a ten cent piece. They were not indurated, were slightly elevated, thinly covered with dull-gray adherent scales. No scarring had taken place. There were also no attacks of recurring hyperæmia, and he was confident the cases were not instances of lupus erythematosus.

The following were then elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. W. A. Hardaway, of St. Louis.

Vice-Presidents.—Drs. J. C. Graham, of Toronto, and A. Van Harlingen, of Philadelphia.

Treasurer.—Dr. G. H. Rohé, of Baltimore.

Secretary.—Dr. W. T. Alexander, of New York.

Mr. Jonathan Hutchinson, of London, England, was elected an *honorary member*.

The following were chosen to *active membership:*

Dr. Geo. H. Tilden, of Boston; Dr. A. R. Morison, of Baltimore; Dr. F. C. Curtis, of Albany; and Dr. L. N. Denslow, of Minneapolis.

The Association then adjourned to meet again on the last Wednesday in August, 1885, at the Indian Harbor Hotel, Greenwich, Connecticut.

CORRESPONDENCE.

THE INTERNATIONAL MEDICAL CONGRESS.

SECTION OF GENERAL PATHOLOGY AND PATHOLOGICAL ANATOMY.

(*From our Own Correspondent.*)

COPENHAGEN, August 17, 1884.

THE Section was opened under the presidency of Prof. REISZ, of Copenhagen, at 10 A. M., August 11th.

The first paper was entitled *Necrosis by Coagulation*, and was read by PROF. WEIGERT, of Leipzig.

Necrosis by coagulation is a process in which tissues are transformed into a substance resembling coagulated albumen; this change has been compared to that forming fibrin and cheese. The change, however, was not explained correctly, being confounded with those in the fibrin of the blood, or in which cheesy change occurred with desiccation and inspissation of the dead tissues. The parts coagulated should be dead, and also have the signs of coagulation from a macroscopic aspect; microscopically this change is characterized by the loss of the cell-nuclei, which, however, may also occur in putrefaction. The following conditions are necessary for this coagulation, viz.:

1. The organs must contain substances capable of spontaneous coagulation, as in all the protoplasms.

2. They must be dead—the coagulation is the *result*, not the *cause;* the latter may be ischæmia, trauma, chemical agents, or microörganisms. The victims may

be either whole organisms (extrauterine pregnancy), or parts (infarcts, diphtheria, cheesy parts of tuberculosis, abdominal typhus, tumors, etc.), or cells (necrosis of kidney epithelium or leucocytes).

3. The dead and coagulated tissue must be in intimate connection with plasma fluids; in order to be this they must be either in the interior of the organs or supplied with living vessels.

4. Agents opposed to coagulation (putrefaction, purulent poisons) must be absent. The fate of these coagulations is softening, calcification, and formation of hyaline substances (waxy degeneration, coagulation of renal epithelium). This hyaline is, however, not a special product.

Macroscopically the tissues resemble the normal ones.

Prof. Virchow differed from Prof. Weigert's views, which he declared were somewhat obscure. He objected also to the name, which might lead to the belief that the death of the tissues is brought about by the coagulation; a better name would be coagulation of mortification. He would rather call it an *Inspissation*. The main question appears to be whether the substance was originally fibrinous material or not; in the latter case, it will not turn to fibrin. The first act in a coagulation is the loss of liquid, which is independent of plasmatic fluids. The fluid does not penetrate, only the water in the tissues is not held, owing to a loss of vitality (plants, infusoria). The retention of liquid in tissues is an act of vitality. We do not know the reason, but believe that the loss of liquid is a sign of lessened life. He does not believe that the change of tissues to the hyaline substance necessitates the absorption of liquid (death of echinococcus). In the dead fœtus also the first occurrence is the absorption of the amniotic fluid. There is no coagulation, but an inspissation; no fibrin is formed. The intercellular spaces disappear more and more, and the external parts may possibly be subjected to a fatty degeneration. The interior parts, however, do not change (*vide* a placenta which he had seen, which had been forty years in the uterus). A parallel might be found in a coagulation of blood found in muscular hemorrhage, where the blood finally is converted into a cheesy mass formed of a compact agglomeration of blood-corpuscles (he had seen it five years old). This is surely an inspissation, no coagulation or new substance.

Regarding the changes in the cells, we find a similar one in carcinoma, when they shrink, the tissue then becoming denser and presenting a homogeneous appearance. He admitted a chemical change in cheesy metamorphosis different from lymph. He could not see any progress in Prof. Weigert's explanation. His view would be important if the process commenced with coagulation, and was followed by death. It would also make a great difference, if the muscles disappeared first and not after the death of the tissues.

Prof. Weigert said the name was suggested by Prof. Cohnheim. He had avoided the word fibrin in describing this coagulation, because fibrin is a chemical term. He was totally opposed to the explanation by loss of liquid.

Prof. Virchow used the word inspissation.

Prof. Weigert might admit partially this word. The loss of liquid, however, is not the primary act, as it would be followed by a loss in size; which is not the case (caseous degeneration of lymphatic glands). In tumors which undergo cheesy degeneration or cheesy pneumonia the cells or affected parts are not smaller than before the change. The loss of liquid or size is a subsequent occurrence, which is independent of the coagulation. The nuclei do not disappear in mummification either.

Prof. Virchow remarked that cheesy glands diminish in size.

Dr. C. J. Salomonsen, of Copenhagen, read a paper on *The Effects of the Infusion of Jequirity*. The ophthalmia caused by jequirity is the result of a chemical poison, which probably belongs to the group of "soluble ferments." The active principle has received the name of jequiritin. The bacteria which are always found in the jequiritin infusions prepared without special precautions have no importance in the causation of the ophthalmia. Such an "ordinary infusion," injected into the dorsal sac of a frog, other conditions being equal, causes death, the time of this fatal result being in direct ratio to the strength of the solution. A "sterile infusion"—*i. e.*, devoid of bacteria, has the same result. The blood of frogs killed by the former infusion is always filled with an enormous quantity of bacteria, while with the latter solution their number is very small. These bacteria do not belong to any particular species, and in the same frog different species may be found. They are not virulent, and injected into the dorsal sac of the frog, or instilled into the conjunctiva of the rabbit, they produce no sensible result. The principle which causes the death of the frog is the same which affects the conjunctiva of the rabbit—*i. e.*, the jequiritin. The blood of frogs which have been killed by a strong infusion of jequirity, produced on injection into the frog a fatal jequiritin intoxication, and with the rabbit the usual ophthalmia. The same does not obtain when the blood of a frog killed by a weak infusion is used. The numerous non-virulent bacteria which are found in the blood of frogs killed by an ordinary infusion originate in this, and by using special care in selecting the bacteria any species of bacillus may thus be multiplied without affecting the final result. But they are not virulent unless mixed with an infusion of jequiritin, and do not multiply in the sac of a normal frog, which has the faculty of eliminating them. The limited quantity of bacteria found after the use of a "sterile infusion" originates probably from the accidental introduction through the liquid covering the frog at the time of inoculation; they do not seem to preëxist in the blood. Dr. Salomonsen's conclusion is, therefore, that after the injection of an "ordinary infusion" the frogs die from a poisoning by jequiritin accompanied by a considerable invasion into the blood of non-virulent bacteria; a poisoning complicated with pseudo-infection and simulating an infectious disease. Rabbits, mice, and chickens killed by an injection of jequiritin, therefore, die from jequiritin poisoning, and not from a disease of bacterial nature. Neither the blood, nor the products of inflammatian in these animals have any infectious qualities.

Prof. Cornil, of Paris, remarking upon these views, said there was no absolute proof of the existence of an alkaloid such as jequiritin. He found it very difficult to make an absolutely sterile infusion, but succeeded by

filtering through porcelain, and found no bacilli under the microscope. This infusion he injected without producing any toxic results. If the active principle was soluble in water, the effect should have been obtained. The substance left in the filter, however, was found filled with bacteria, and caused intoxication by injection. These bacteria he had cultivated, and even in the fourth culture obtained toxic symptoms. The sterile liquid, after being exposed to the air, caused death within twenty-four hours. He heated a jequirity maceration, when it became non-virulent, but on adding bacteria it became toxic. He, therefore, believes that the bacilli are the active principle.

Dr. Salomonsen replied that he had not said the bacilli had nothing to do with the intoxication, only that they were innocuous in a *sound* animal; as soon as the fermentative action of jequirity has taken place they become toxic. As to jequiritin being only a name, he admitted that, like all soluble ferments, it is not chemically well defined. Regarding the filtration, the ferment might be retained on the filter as it is in dialysis, hence the filtered infusion might be devoid of it; consequently that argument is not conclusive, to establish it it would be necessary to obtain a sterile liquid, filter it, and then fail.

The next article was on the *Staining of Bacteria in Sections*, by Dr. Chr. Gram, of Copenhagen. The purpose of the paper was to show that the bacteria of pneumonia and typhoid fever can easily be stained by dipping them in a concentrated solution of gentian violet, and then fixing the color in a one per cent. watery solution of corrosive sublimate. He reported that Dr. Friedlander succeeded in obtaining excellent staining of sections with coccobacteria by immersing them in a solution of 1 part of fuchsin, 100 of distilled water, 5 of alcohol, and 2 of glacial acetic acid, after which they are washed first in alcohol, and then during two minutes in a two per cent. solution of acetic acid, subsequently cleaning them as usual in alcohol and oil of cloves.

Prof. Malherbe, of Nantes, then read a paper on the pathological anatomy of *Painful Subcutaneous Tubercles*. This disease is rare, he has only seen it five times in ten years (syn. painful fibroma). The tumors are from the size of a lentil to that of a filbert, and are noticed by the extreme sensitiveness to touch, which gradually turns into a spontaneous neuralgia. Their usual seat is in the vicinity of the malleoli and the knee, and they generally occupy the deeper layer of the skin, or the subcutaneous tissue. Anatomically they are composed of organic muscle-fibres, crossing each other in every direction, encased in a thin capsule. No nerve-filaments were discovered. Extirpation gives immediate and permanent relief.

Prof. Pasteur, of Paris, in general session, read a paper on *Morbific Microörganisms and Vaccinia-matter*. He was most enthusiastically received. He first referred to the advances made in the study of microörganisms since the last Congress. Three years ago, at London, no one thought of believing in the microbic origin of contagious diseases. From that time also dated the doctrine of attenuation of virus by the culture of the microbes, the discovery of the anthrax vaccine, and the cholera bacillus. Four years ago he commenced his studies of hydrophobia, which, owing to the length of incubation in the animals operated on, became protracted. He would give to-day his results. Of course, in a dreadful disease like hydrophobia, the first thought was to find a remedy, but in order to discover this the nature of the disease had to be known. Numerous dissections of dogs which had succumbed to the disease, showed that its seat was in the brain and spinal cord, but more especially in the medulla oblongata, this latter being constantly affected. Foci of inflammation were found in different parts of these organs, and were in direct proportion to the severity of the case. The principal seat of the poison is in the subarachnoidal space. The arachnoid liquor, which never fails in inoculation, was used for experimental purposes, and trephining employed to lay bare the dura mater, under which the virus was injected by a Pravaz syringe. This is the only absolutely certain mode of inoculation. Thanks to this positiveness of results, he could advance with his experiments on a sure basis. This mode of inoculation also shortened the period of incubation, a matter of great moment in such lengthy experiments. The duration of incubation was found to be in direct proportion to the quantity of virus introduced.

Here Prof. Pasteur gave the results of numerous experiments, mentioning each, a relation of which would prolong this account too much.

He found that in rabbits, after subarachnoidal inoculation, the time of incubation at the first injection varied from fifteen to twenty-one days, never more and never less. Virus taken from the first rabbit would lead to rabies in a second in twelve days, the next ten, the next eleven, until the twenty-first inoculation, when to the fiftieth there was an absolutely fixed incubation of ten days. Guinea-pigs have an incubation of five days—five or six cultures lead to the maximum of virulence. Monkeys have an incubation of twenty-three days, virus obtained from them caused a longer incubation in the rabbit, and by passing a number of times from rabbit to monkey the activity of the poison, instead of increasing as it did in direct transmission in the rabbits, became lessened and the time of incubation lengthened. The microbe of hydrophobia has not yet been discovered.

He then gave an account of his last great test of the efficacy of this attenuated virus. A distinguished commission was assembled in Paris to examine into his experiments, and to these gentlemen he delivered twenty-three vaccinated dogs, sixteen of which had been vaccinated by trephining, the remainder hypodermically. These dogs were at different times shut up with rabid dogs and were frequently bitten—a certain number of unprotected dogs were treated likewise. All these experiments were made a short time ago. The result was that of the vaccinated dogs none suffered any ill-effects, while already four of the unprotected dogs have died from rabies.

This is only a sketch of a discourse which lasted an hour and a half, and was followed with the closest attention and frequent loud applause.

The work of the Section was resumed on Tuesday, at 10 A.M., with a paper by Prof. Raymondaud, of Limoges, on the *Ixodes, a Parasite but Little Known in the Human Body*. He exhausted the natural history of the different species of ixodes (tick), and related a few cases in which the bite of this arachnid was followed by

ulceration, and in one case it was supposed to have caused death. The paper was very exhaustive, but scarcely belonged to the class of subjects which one would expect to find discussed in such a galaxy of pathologists as were present.

The discussion was opened and closed by Prof. Virchow, who, with his incisive humor, remarked that the animal was very common in Germany, that when it had fastened in the skin it was lifted out with a needle, and that he had never heard of any ill-effects resulting.

This paper was followed by one from PROF. HELLER, of Kiel, on *The Heredity of Tuberculosis*. He said that the views held up to the present time, that tuberculosis can be transferred to the fœtus at the moment of fecundation or during its uterine life, is no longer tenable. The proofs heretofore adduced in favor of the old theory can be explained otherwise. There is a possibility of this transmission, but facts speak against it. He based his view on observations made in 1300 cases. Tuberculosis is, if it ever occurs, very rare in the fœtus and the new-born child up to the end of the first few weeks. It appears only toward the end of the second month after birth, and its frequency rapidly increases from that time. The mode of its conception speaks against the supposition of intrauterine origin. When apparent cheesy degeneration of the lungs was observed in the fœtus, it was generally found to originate from hereditary syphilis.

A certain predisposition, however, must be admitted in the progeny of tuberculous parents, but it has been contended that when the child was not allowed to nurse from such a mother, the chances were in favor of its immunity.

Prof. Heller then related a case of pregnancy in a tuberculous mother, who died before giving birth. The fœtus was perfectly sound—the mother suffered from general tubercular degeneration of all the organs, even the uterus was degenerated, and a preparation, exhibited under the microscope, showed large quantities of tubercular bacilli in the epithelial cells.

The discussion was again opened and maintained by PROFESSOR VIRCHOW. He said that thirty years ago he had disputed the heredity of tuberculosis. He, however, admitted the predisposition. He had not seen a single case of direct transfer in the fœtus; where there seemed to be such an appearance, it would only be an isolated case of spontaneous origin. He would like to have a closer definition of the term predisposition. Thirty years ago it was explained on the principles of humoral pathology, but he did not attribute it to the blood—rather to a lessened power of resistance in the tissues. He desired to talk again on the subject. He believed that the key could be found in the peculiarities of the lymphatic system, which varies in every individual. It evidently, under the influence of this weakening of the system, deteriorates from one generation to another, until, as we have often seen, whole families are wiped out of existence; fatal results appearing at a more and more early age.

PROFESSOR HELLER remarked that he had not denied the heredity of the *predisposition*, only the direct transmission of the disease to the fœtus. He believed, however, that the mucous membranes have more to do with the susceptibility to the infection, and that persons with rapid changes in their mucous membrane will be more apt to throw it off than those whose membranes are not active.

The next paper read was by DR. GRANCHER, of Paris, on the *Relation between Scrofulosis and Tuberculosis*.

PROF. PASTEUR here entered unostentatiously, but was vociferously applauded, and conducted to the presiding chair.

After giving a historical review of the history of scrofula and tuberculosis from the sixteenth century to the time of the doctrines of Virchow and Borzin, in 1860, Dr. Grancher showed that by the aid of pathological histology and the knowledge of the different phases of evolution of the tubercle, the domain of tuberculosis has been enlarged at the expense of scrofula, and has absorbed fungous osteitis, lupus, and cold abscess. The discovery of the virulence of the tubercle and of the tubercle bacillus has completed the demonstration.

There is nothing left to scrofula but a few skin diseases like eczema and impetigo, and a few diseases of the mucous membranes which scarcely display more than a morbid disposition. The researches of Dr. Grancher were mainly directed toward establishing the question if the discharge of these skin diseases, especially impetigo, or inoculation would produce the changes of tuberculosis. The experiments were made on the guinea-pig, and were negative, while in every instance control-injections of tubercular matter produced tuberculosis. He related twenty-three experiments, twenty-one of which remained negative as far as discharges derived from impetigo and mucous secretions were concerned; in two cases, however, caseous degeneration took place, but it must be remarked that in these cases the virus was not taken from the impetiginous discharge, but from an adjoining small abscess.

The discussion was opened by PROF. LANGALLI, of Pavia, who remarked that many diseases declared by physicians as scrofulous are really tubercular, such as osteitis, periostitis, etc. He believed that there is no difference in the lymph-ganglia of tubercle and scrofula, and that the lymphatic bodies in both assume the same changes, and that giant-cells and bacilli are found in both. He believed that scrofula is the prodrome of tubercle, and will end in it if not cured, and that it has its origin in disorders of the digestive organs.

PROF. CORNIL, of Paris, believed that the discovery of the bacillus settles the question of identity between scrofula and tubercle. Dr. Grancher's failure in two cases to prove immunity of the scrofulous discharge is probably due to the fact that the abscesses from which the virus was taken were of tubercular character. He believed that what mostly ought to be kept in mind here is that many diseases which formerly were classified with scrofula are now known to belong to tuberculosis.

DR. GRANCHER mentioned that probably the only difference between the two diseases is that one is caused by an "exalted" virus, while the other is the result of an "attenuated" virus, a view which is entirely supported by the researches of Prof. Pasteur; but he believed that this Congress will not bring this question to a conclusion.

PROF. WEIGERT, of Leipzig, did not believe in this theory of attenuation. He thought that the disease is localized in the lymphatic glands. In children, changes take place in these glands without being of tubercular nature; with adults, tubercular disease occurs without

implication of the glands. The former, he claims, is due to the capsule of the gland, which prevents the dissemination of the disease, while in adults the bacilli are absorbed through the mucous tracts. In adults tuberculosis appears first in the apices of the lungs, in children in the hilus, the latter caused by the eventual perforation of the capsules of the lymphatic glands around the hilus, and the favorable prognosis in children must mainly be based on localization, and not on attenuation.

Dr. Grancher thought this view reasonable, but found the following objection to attributing the difference in the two diseases to age: 1. Scrofula is not confined to the child. 2. Adults have diseases of bony tissues, which usually pertain to childhood. 3. Children are not free from tuberculosis. Besides, the histological differences are very pronounced. He did not mean to say that vaccination of attenuated virus would protect against tuberculosis.

Prof. Weigert desired to state that he did not mean to convey the idea that only children have localization, but that most frequently such is the case.

During the general session in the afternoon Prof. Verneuil, of Paris, read a paper on the *Neoplastic Diathesis*. He attempted to prove by ingenious arguments, based on clinical observations, that all neoplasms which are not the result of a specific disease, are the result of a diathesis, which, according to the peculiarity of the individual, will in one case produce sarcoma, in another lipoma, in another cysts, etc.; that the number of neoplasms has nothing to do with the diathesis, and that the diathesis may produce neoplasms of different character in the same person, the whole of them partaking of the nature of a hyperplasia of the normal tissues; that their cause is pathological, the growth physiological, the immediate existing cause being either irritation, or of an idiopathic character.

Prof. Cornil, of Paris, then read in the Section a paper on *Chronic Nephritis*, especially on the relation of the changes of connective tissue, parenchyma, bloodvessels, and heart in this disease.' His views can best be condensed by giving his classification of the different kinds of albuminous nephritis:

1. Diffuse nephritis with—

a. Predominance of congestive and inflammatory phenomena. *b*. Predominance of diapedesic phenomena. *c*. Predominance of degenerative lesions.

2. Diffuse subacute and chronic nephritis with—

a. Predominance of lesions of glomeruli. *b*. Predominance of lesions of epithelium. *c*. Predominance of lesions of interstitial tissue.

3. Interstitial nephritis or necrosis.

a. Cirrhosis of glandular origin. *b*. Cirrhosis of vascular origin (interstitial necrosis proper).

Prof. Cornil presented original researches on interstitial nephritis artificially produced in animals by lead poisoning. The kidneys show on transverse section of the pyramids in the centre, a fibrous zone with atrophic tubes, in the periphery a zone formed by the glomeruli surrounded by interstitial tissue and an intermediate fibrous zone with urinary tubuli, part of them atrophied, others almost sound, constituting the granulations prominent on the surface of the kidney. The elimination of the lead salts and the resulting deposits of calcareous salts are the cause of the chronic inflammation which terminates in atrophy of the epithelial cells. In the commencement the bloodvessels are normal, and their walls become thickened only after the renal sclerosis is already well advanced. Albuminuria is not present in the guinea-pig, in the human being it may or may not be present; but in the chronic saturnine nephritis of the latter, coexisting with albumen, he found cellular lesions analogous to diffuse nephritis. Sometimes cysts form at the expense of the dilated tubes. The vessels which pass through the sclerotic tissue are in themselves sclerotic, but the larger arteries are not affected. Coexisting, he often noted hypertrophy of the left side of the heart, and deposits of sodium urate in the articular cartilage, especially in the phalango-metatarsal joint of the great toe, resembling those of gout.

Sir William Gull presented a paper on the same subject. After introductory remarks on the fallacy of Bright's views that renal lesions are always of one form and character, have local origin, and are the source of the systemic lesions which are associated with them, with a vague idea that albuminuria indicates one pathology, the speaker attributed to an arterio-capillary fibrosis, which may begin in any part of the vascular area, the cause of nephritis. This, even with cardiac hypertrophy, may precede defect of renal functions. In this cachexia the intima and adventitia of the arterioles and capillaries are changed by fibroid or hyalin-fibroid deposit. The muscular coat is thickened. Death may occur from cerebral hemorrhage with cardiac hypertrophy, whilst the kidneys are found but little affected. The fibroid change in the kidney has no acute, inflammatory beginning, and its early stage is coexistent with vascular changes in other organs. The same condition of the vessels is found in other organs, as the lungs, stomach, skin, with or without renal disease, proving that the renal change has common characters with those more widespread through the organism. The hypertrophy of the heart is to be attributed to loss of arterio-capillary elasticity and hinderance to interstitial circulation of plasma; whilst in the cases in question the arterio-capillary changes cannot be referred to the kidney as their source, it still remains to be determined how far a change, beginning in the kidneys, may promote a cachexia inducing arterio-capillary fibrosis.

Prof. Heller, in about one hundred cases, had not found the fibrous thickening.

Prof. Prévôt found incrustations with calcareous salts (calc. carb.) in the kidneys in consequence of mercurial poisoning, with lessening of urinary secretion. In saturnine poisoning he found the same in the form of phosphates of lime.

Prof. Cornil remarked that Sir W. Gull had left the domain of special pathology to discuss the subject from the point of view of general pathology. Special pathological researches cannot be formulated in that manner. Sclerosis commences in the walls of the tubes, and from there proceeds to the interstitial tissue and is of an epithelial origin. He cannot consider saturnine nephritis as a result of arterio-capillary sclerosis, as it is characterized at its outset by infarctions caused by elimination of lead salts and also by cell lesions; then come atrophy, collapse of the tubes, and the condensation of the connective tissue. Only long after this we observe the chronic arteritis. Considering that a rational classification of lesions has to be based on the origin and

development of disease, Prof. Cornil adheres to his view of two varieties of renal cirrhosis—that of glandular origin (saturnine and gouty nephritis), and that of vascular origin.

Prof. Mahomed, of England, believed the change to be due to contraction of the arteries and consequent slowing of the movements of the blood corpuscles. This may be transient, but also chronic, as in gout, dyspepsia, saturnine poisoning. The first factor is altered blood, then come the changes in the kidneys, and, last, those in the vascular system.

The next paper was that of Prof. Chauveau, of Lyons, on the *Possibility of Animal Tuberculosis becoming a Source of Human Tuberculosis*. Nothing is easier than to communicate tuberculosis to the animal; the guinea-pig and rabbit are especially susceptible; only the horse and donkey are refractory. Few species, however, produce idiopathically tuberculosis—only the pig and the beef. In the former it is exceedingly rare; in the beef, however, frequent—about one and a half per cent.—consequently this latter animal alone may be considered as possibly dangerous in that respect. He introduced tubercular infection from the beef into calves by way of the stomach (mixed with food), and they all became tubercular; any other pus was inert. It is therefore proved that the disease can be propagated from beef to beef. To prove the unity of tubercular matter in beef and human species, disputed by Virchow, calves were fed from human tubercular pus, and infection was the result. There is consequently a great danger of infection from the beef. This may be communicated in three ways: by the eating of beef, the use of milk, and animal vaccination. Statistics on the first are not complete, but lean rather to the negative; on the second we will hear a paper from Prof. Bang, with which he coincides; he will here principally speak of the third.

The first reason for bovine vaccination was to avoid the danger of syphilis. This practice has a great advantage on that account. He has made experiments as to the possibility of inoculating tuberculosis in using bovine virus. He injected vaccine matter from a tubercular cow into pigs and rabbits, and they all died from tuberculosis. Experiments on guinea-pigs vaccinated with vaccine virus from tubercular persons had negative results. Tuberculosis is very rare in young calves. He found it very difficult to produce it in animals by superficial scarifications as practised in ordinary vaccination. In five cases vaccination on erosions or by subcutaneous injection was negative as far as producing tuberculosis in calves; the same results were obtained in the guinea-pig. His conclusion was that if there is a possible danger of introducing tuberculosis by bovine virus, it is almost entirely neutralized by the nearly total impossibility of communicating it through the usual process of vaccination.

Prof. Vallin, of Paris, found that *localized* tuberculosis in the beef does not produce tuberculosis in the guinea-pig on injection of the macerated juice of the muscular tissue. He stated that according to Prof. Chauveau's percentage of tuberculosis in beef, there were consumed, in Paris, last year over ten thousand tubercular beeves, slaughtered there (not counting the imported meat), and that only eleven carcasses were rejected by the inspectors for that cause.

Prof. Salomonsen caused tuberculosis in the guinea-pig by injecting tubercular matter into the anterior chamber of the eye, but *blood* from tubercular animals, injected in the same manner, gave negative results. Injections into the peritoneal cavity of a guinea-pig with tubercular blood from another were likewise negative.

Prof. Chauveau had made many experiments on the virulence of the *blood* in tuberculosis, and found that it is not virulent. He has had the same experience in glanders, where injection of the lymph reproduced the disease, but blood did not. The same in variola of sheep. His experiments on the juice of meat are not completed and are not so conclusive. Meat juice from tubercular beef, injected into a large number of guinea-pigs gave negative results, while matter from tubercular lymphatic glands caused tuberculosis in every case. Cooking for one hour at 70° R. did not destroy its virulence; at 100°, with one-half hour's cooking, however, it was lost.

Prof. Cornil thought that the same obtains with the vaccine matter as with the blood, and that the question of possibilty of tubercular infection by vaccine lymph, must be decided in the negative.

The next paper was by Prof. Bang, of Copenhagen, on *Tuberculosis of the Udder of the Cow*. This is not rare. He has seen twenty-seven cases; seven during the last seven months. The diagnosis is easy. A diffuse, painless, gradually hardening tumefaction of usually one-quarter of the udder takes place, without impairment of health or decrease in the quantity or appearance of the milk (this is important because this milk already holds tubercular bacilli, and is still used as food. When bacilli are associated with spores, according to Koch, they resist the action of the gastric juice). Gradually, usually not before a month, the secretion of the gland assumes a watery, flocculent appearance, but is not purulent. The animals generally perish inside of three months. Injection of the milk produced death from tuberculosis in rabbits in from two to three months. The later serous secretion caused fatal results from tubercular peritonitis in twenty days. Experiments of feeding rabbits on this milk have not yet been concluded. He found that milk from a tuberculous cow, without localization in the udder, was virulent. Heating to 212° F. destroyed the vitality of the bacilli.

Prof. Heller, of Kiel, then made some remarks on *Congenital Syphilis of the Lungs*, illustrated by sections under the microscope. The main anatomical change found is a capillary hyperplasia in the interstitial tissue, with hypertrophy of the right ventricle. The children usually die before the end of the first year.

Dr. Nelson, of New York, presented a paper on the *Culture of Diphtheritic Microbes*. He assisted last November in tracheotomy on a diphtheritic child. A membranous cast was removed. The child died thirty-six hours later. He inoculated one of Sternberg's culture bulbs with some of the membrane. (For culture, the bulbs should be kept at 100° F. for several weeks.) In four days the sterile liquid became cloudy, and with 1000 diameters, immense quantities of micrococci similar to those of pus were found, which he propagated successfully through ten generations. This propagation usually took ten days. He inoculated three guinea-pigs in the anterior chamber; one died in thirty-six hours. two were killed in three days. In all the eyeballs were

destroyed, and micrococci were discovered in large numbers. He believes that there is a micrococcus of diphtheria which will reproduce the disease in guinea-pigs.

The last discourse was by PROF. VIRCHOW, on *Forms and Causes of Hepatitis*. While in nephritis the arteries play the principal *rôle*, in hepatitis the veins are the affected part. It is difficult or impossible to follow the changes proceeding from the capsule of Glisson to the nervous and arterial system, but he believes that a chronic fibrosis affects the veins and bilious ducts. This fibrosis is unequal; the liver has a tubercular surface, the depressions being the result, the tubercles the original line. This is particularly striking in syphilitic forms. For localization of the latter some natural factor may be the determining cause; as we find a gummatous tumor originating from a contusion of the forehead, so in the liver the minute superficial ruptures caused in concussions, especially along the ligaments, may be the exciting cause, and these changes are also mainly found along these ligaments; other causes for these localizations are so far not known. Those who reduce all affections in anticipation to microbes, may also find an explanation, without actually demonstrating the microbes. In opposition to this view, he gave examples in which the predisposing cause is a *chemical* poison. Thus minimal doses of phosphorus will produce a cirrhotic condition of the liver (experiments on chickens). But even here the actual cause is unknown. The cirrhosis is uniform in acute phosphorus poisoning, while in the chronic form its distribution is irregular. We may find a parallel in the malarial liver. In common with syphilis, it appears in different forms, but has not the large foci of the syphilitic liver, and might best be likened to a general induration, and it may become granular with irregular distribution. It has also frequently a melanæmic appearance, leading to possible confusion with putrefaction. Frerichs believed this to be a result of embolism, but Virchow has examined many cases, and found only the usual contents of the vessel, but there was a melasma with black connective tissue due to pigment in the cells. This may be produced by other causes than malaria, but he knows of none. Here, also, the reason why it is unequally distributed is not known. He also referred to alcohol as a cause for fibrosis. We have, therefore, four different causes for bringing about parallel changes, viz., syphilis, phosphorus, malaria, and alcohol.

One more point is important. Cirrhosis frequently occurs with chronic peritonitis, often also with the appearance of tubercles, which, however, have no tendency to produce the cirrhotic change, and differ from the appearances in general tuberculosis. These simple forms are complicated in many ways in nature.

As to predisposition, it may be found in the peculiarities of the anatomy differing in every individual in the normal state, especially as to the size, and, consequently, the number of the acini and their supply of capillaries (different arrangement and quantity of vessels). This will explain the fact that the diseases originating from the same cause show various effects in different individuals. We must always consider the cause by itself, and the local result by itself.

In reply to a remark of Dr. Fränkel, referring to hyperplastic changes, Virchow said that he had seen both in the same case, resembling externally carcinoma.

PROF. HELLER mentioned that he had also seen the so-called hypertrophic form without apparent tendency to shrink, with no malaria for a cause. Another possible cause which has not been mentioned is strong spices, which, he believes, may irritate the liver.

This last discourse of Prof. Virchow having been made without notes, was, as usual under such circumstances, at times disconnected, and it was difficult, often, to follow the main thread.

THE SECTION OF DERMATOLOGY AND SYPHILIS.

(*From another Correspondent.*)

COPENHAGEN, August 17, 1884.

THE Section of Dermatology and Syphilis opened at 9.30 A.M., with THE PRESIDENT, DR. HASLUND, of Copenhagen, in the Chair.

PROF. DOUTRELEPONT, of Bonn, read a paper on *Lupus Vulgaris*, holding it to be tubercular in origin and nature. The discussion was participated in by Leloir, Kaposi, Neisser, Unna, and others.

PROF. KAPOSI held that we must distinguish between lupus vulgaris and tuberculosis of the skin; that they are two separate diseases. Of the latter he had seen thirteen well-marked cases, ten in the clinic, and three in private practice. Prof. Pick agreed with Kaposi. Leloir thought, with Koch, that there was a bacillus in lupus; and Neisser, Doutrelepont, Unna, and Lipp concurred in this view.

On August 12th, PROF. KAPOSI occupied the Chair. The first paper was by Dr. Armauer Hansen, of Bergen, on *Norwegian Leprosy, its Etiology and Pathology*. He presented three marked cases which he had sent to the meeting for exhibition, from Norway. One was especially interesting, as showing the results of the disease, having the phalanges of both hands and feet greatly distorted, with even a loss of several. The muscles of the face were so atrophied as to make it impossible to bring them into action, and the eyes remained widely separated even during sleep. He observed a vast difference between the knotty and the smooth variety. The course is regular until anæsthesia sets in, when he could stick a knife into the patient without the least pain. Even limbs could be amputated without pain. Patients with the knotty variety may die of the disease, the usual course being to succumb to the sequelæ. There are various clinical phenomena which speak for the contagious character of this disease. "Looking toward the etiology, it must be remarked that inheritance and contagion bar each other; so that we have no contagious disease which is at the same time inherited." The bacillus lepræ has not yet solved the question, but has shown as quite probable the contagious nature of the disease. Isolation is the best preventive measure, as was shown by a series of statistics.

PROF. ZAMBACO, of Constantinople, presented a number of plates illustrative of leprosy.

PROF. PICK, of Prague, read a very exhaustive paper on *Excision of the Initial Sclerosis of Syphilis*. He cited many cases to substantiate his views, and came to the conclusion that excision should be done even in doubtful cases, so as to give the patient the benefit of the doubt. Besides, a clean cut heals by first intention, whereas the sore, if left, or otherwise destroyed, will remain indefinitely.

DR. PONTOPPIDAN demonstrated the views of Prof. Pick in several cases, and coincided in the opinions he expressed.

PROF. MARTINEAU, of Paris, said we should be very careful to diagnosticate between induration and sclerosis, and not cut every case.

The Section adjourned to meet on the 14th, when PROF. PICK occupied the Chair.

DR. GRUNFELD, of Vienna, exhibited an *Endoscopic Case* of his own design, with various sized tubes and a mirror such as is used by laryngologists. He showed, by drawings, how different portions of the urethra presented different pictures, and each very characteristic of its situation.

PROF. LIEBREICH, of Berlin, read a paper on the *Treatment of Syphilis by the Injection of Mercury*, and made many interesting chemical tests to prove which salts of mercury were the best to use. He thinks that besides corrosive sublimate, formic acid is the best. When mercury ceases to act, the original susceptibility can be restored by a good diet with an abundance of salt, when more of the mercury will be again absorbed.

DR. WULFF, of Strasburg, said it should be our object to select a remedy that would be as nearly painless as possible, and that we should recollect that besides the disease we still have a patient to deal with. Profs. Martineau, Bergh, Lipp, Neisser, Kaposi, and others, did not favor the injections as being better than other methods.

PROF. KAPOSI said the injections appear at first to be the best, but after a while they lose their effect, whereas inunctions do not give at first such brilliant results, but by-and-by they prove more satisfactory, and in the end achieve better results. After considerable discussion it seemed to be the prevailing opinion that no one method was yet settled as *par excellence* the best.

On Friday, August 15th, PROF. DOUTRELEPONT occupied the Chair.

PROF. LANG, of Innsbruck, presented a paper on the *Combination of Carcinoma and Gummata*. He showed a series of photographs and diagrams to illustrate his views, and one case, he said, was undoubtedly marked. He had been unable to find any history of cancer, or the existence of it before the appearance of the gummata, and was of the opinion that it came on after the latter had healed.

DR. BARTHÉLEMY, of Paris, then read a very interesting communication on the *Visceral Manifestations of Late Hereditary Syphilis*.

PROF. NEISSER then spoke of the *Period of Cessation of the Contagion of Gonorrhœa*. He said it was difficult to settle such a question unless we know absolutely the last act of coitus, and as long as the bacillus exists it is contagious, and he would not advise marriage. He thought probably three months long enough.

On Saturday August 16th, PROF. THIN, of London, occupied the Chair. As this was closing day, he requested that the debates be limited so as to allow all papers to be read that were on the programme.

PROF. JANOWISKY, of Prague, read a paper on *Iodoform-exanthem*, and he reported that he had seen many cases the result of the absorption of the drug.

PROF. HASLUND had used iodoform very extensively, but had only seen one marked case, which occurred on the third day after the extirpation of a bubo, and the wound was packed with iodoform. There was no fever, at first vesicles appeared, then pustules, and in a few days these dried up.

DR. HASLUND, of Copenhagen, read the closing paper on the *Pathogenesis of Gonorrhœal Rheumatism*.

PROF. DOUTRELEPONT, in the Chair, then thanked the President, Dr. Haslund, and the secretaries for their services, and again wished to renew his thanks and that of the members to the committee for their successful management of the Congress. The Section then adjourned.

THE BERLIN LABORATORIES.

BERLIN, August 18, 1884.

A SHORT account of the Berlin laboratories, the work of which has a direct bearing upon medicine, may possibly prove interesting to the readers of THE MEDICAL NEWS.

And first of all, of chemistry, to which directly and indirectly medicine owes so much and to which in the future, possibly the near future, it is likely to owe much more. There are several good chemical laboratories here in which a "mediciner" may work. That of Prof. Hofmann, on account of the fame of its "director," is filled and more than filled. The regular lectures on chemistry are given three times weekly, in sessions of two hours each. They are most admirably illustrated by experiment, and the subjects dealt with rendered very clear, in fact, some think there is an excess of simplification, but this is a good fault, if fault it be.

It is well for any foreigner, who may wish to obtain a place in this laboratory, to know that it will be necessary to apply long before the expected period of work, and even then he may find, as I did, that a place in "Hofmann's Laboratory" does not mean necessarily a place under Prof. Hofmann himself. I was, in fact, consigned to another department of the laboratory which the distinguished professor himself never even visits so far as I know, and which is presided over by another professor. As my own experience of this latter department of the laboratory does not enable me to speak favorably of it, and as such experience may possibly be exceptional, and I sincerely hope it is, I pass this laboratory by without further remark.

I have heard Prof. Liebermann and his laboratory well spoken of, but know nothing of them from personal experience.

Of laboratories for physiological chemistry there are several in Berlin, each of them under the direction of a teacher of distinction. The oldest of these is that in the Pathological Institute in connection with the Charité. It was founded as far back as 1856, at a time when laboratories for physiological chemistry, even in Germany, were very insignificant as a rule, This laboratory is a monument of the insight of the great Virchow, to whom it owes its existence. Even at this early period Virchow could see the relation and importance of chemistry to medicine, which not a few of some standing in our profession seem not yet to realize. Such distinguished men as Hoppe-Seyler and Kühne, have had a connection with this laboratory in earlier days, and it is now presided over by Prof. E. Salkowski, who has recently become still better known since the publication, in conjunction with Leube, of his large and elaborate work on the urine. From personal experience of this

laboratory, I can recommend it to anyone wishing to work on medical chemistry, whether physiological or pathological. The Physiological Institute has also an admirable laboratory for physiological chemistry under the direction of Dr. Kossel, who was till recently an assistant of Prof. Hoppe-Seyler in Strasbourg.

It is remarkable how many "practical physicians" still, at the age of thirty-five to forty, manage to maintain a lively interest in physiology, and often undertake investigation either in the chemical or experimental department. Sometimes this work has a direct reference to practical medical questions, and sometimes seems to be done purely to maintain an old scientific love. They have never been, in fact, divorced.

The Institute for Physics under the direction of Helmholtz, that for Physiology under Du Bois Reymond, and that for Pharmacology under Liebreich, are so close together that they form one magnificent and compact pile, only surpassed in beauty by the Military Academy opposite. A course on physiological optics is being given in the Institute for Physics, but the "mediciner," who would get much from this, must be well versed in mathematics. The case is entirely different with another course on physics, viz., that given in the Institute for Physiology by Prof. Christiani. This course is especially designed for the "mediciner," and comprises what is most important for the understanding of experimental physiology, the microscope, etc. The sessions are of two hours' length, and occur twice weekly. The experiments are most admirable and leave little to be desired. The course is modelled somewhat after Tyndall's public lectures, but is still different in that theory is somewhat more prominent, and the mathematics of the subject are not neglected. However by the use of the *graphic method*, many mathematical formulas, which otherwise would be very difficult for such auditors, are rendered clear. The same remark applies to the more difficult theories, such as the different wave theories. Altogether the course is *unique*, and the teacher of any department of experimental science can get many valuable suggestions as to the best methods of making his subject clear and impressive.

Physiology is in a highly flourishing condition in Berlin. Reference has already been made to the abundant provision made for physiological chemistry. A course of lectures on general physiology is given at the excellent Veterinary School here by Prof. Munk. They are both clear and well adapted to the hearers. The principal course of lectures in the Physiological Institute is given by the venerable and long famous director, Prof. Du Bois Reymond. His lecture-room is large, comfortable, and exceedingly elegant in all its appointments, and the lectures are illustrated with the most beautiful and best adapted apparatus to be had.

Prof. Hugo Kronecker also gives one lecture a week on the physiology of the heart and one on muscle physiology, both in much detail and well illustrated.

In the experimental department of physiology, the laboratory work devolves mostly upon the energetic and accomplished professor just named.

Apart from conducting many special researches, a course on "methods of investigation" in physiology is given. In this course vivisection and the graphic method are taught very much apart, and in general the separation of what may be called the *technique* of physiology from the theory, and the facts of the science observed in this laboratory seem to me worthy of much consideration. How much loss of time and confusion of ideas is avoided by such a course, only those who have seen the reverse method pursued can thoroughly appreciate. I should be glad to see such a separation in some way applied to chemistry and some other departments, for I know of no laboratories in which so much time is simply pottered away as in chemical laboratories. A preliminary course on *technique* or manipulation would obviate much of this and also probably prevent the student from becoming the merely mechanical worker. Prof. Kronecker's full course in "methods of investigation" extends over four semesters or two years. I must not omit to remark upon the exceedingly courteous, in fact cordial treatment, all students, including foreigners, receive in this professor's laboratory. Here, at least, the man and the gentleman are not forgotten in the student, nor lost in the professor.

From what has been said, it will appear that ample provision is made in the Berlin Physiological Institute for the teaching under the best conditions of the physics of medicine, the chemistry of medicine, and the experimental physiology of medicine; and it only remains to add that a full course in histology, etc., is given under Prof. Fritsch, to indicate how thoroughly this Institute deserves its name.

The adjoining pharmacological laboratory under the direction of the well-known Liebreich, is, in the completeness of its various departments, perhaps unequalled anywhere in the world. No expense seems to have been spared to make it as nearly perfect as possible for the purposes, both of teaching and of investigation. A noteworthy regulation exists requiring all students to take a course of instruction in antisepsis, and a special department of the laboratory is devoted to this purpose.

The Berlin Physiological Society has a large membership, and the attendance at the meetings, which are held every two weeks, is uniformly good. Prof. Du Bois Reymond occupies the presidential chair. Abundance of material in the form of papers is forthcoming, and each communication is subjected to the keenest criticism by those well able to discuss any physiological question that may arise.

Other laboratories having a relation to medicine might be referred to. In conclusion, I may be allowed to express the hope that before long the authorities of the Berlin University will see fit to abolish the regulation by which all foreigners, irrespective of age and *status*, are obliged to pay a matriculation fee and go through all the forms (and these are not a few) pertaining to matriculation, before they can participate in the advantages offered by this great University.

T. W. M.

NEWS ITEMS.

The College of Physicians of Philadelphia on Monday evening gave a reception to the members of the British and American Associations for the Advancement of Science who were in attendance upon the Philadelphia meeting. The building was beautifully decorated with flowers and plants, and the Library and Museum were open. Refreshments were served in the Lecture Hall.

This was the first of the series of entertainments provided for by the Weir Mitchell Entertainment Fund.

Dr. John G. Adams's Medical Bequests.—Dr. John G. Adams, of New York City, by his will dated June 21, 1881, has left $5000 to the Presbyterian Hospital for a free bed for the sick poor of the Brick Church; $5000 to the Academy of Medicine to pay off the debt on its building (this bequest is revoked by codicil on account of the action of the Academy in reference to the new code); $2500 to the Bridgeport Protestant Orphan Asylum and Hospital; $500 each to the Physicians' Mutual Aid Association, and the Training School for Nurses. His medical library is bequeathed to the New York Academy of Medicine.

The Consolidation of the Medico-Chirurgical College with the Philadelphia Dental College.—We understand that a consolidation of these two schools has been effected, and while each will for the present maintain its separate organization, the students of the former will receive instruction in surgery, physiology, and chemistry at the Dental School, while the dental students will receive clinical instruction in other subjects than dentistry at the former.

Cholera Mortality at Marseilles.—Dr. Albenois, of Marseilles, in the monthly *Bulletin* of the Bureau of Statistics for July, gives some very interesting statistics relative to the epidemic of cholera in that city. From June 27th, the date on which the disease was recognized as true cholera, to August 4th, the deaths numbered 1311, of which 844 occurred in the city, 163 in the outskirts, and 304 in the hospitals. The period during which the disease seemed to have reached its maximum of fatality, was from July 11th to July 26th, in which period there were 853 deaths, a daily average of 51; from July 26th on there was a marked and steady decrease in the deaths. Of the decedents, 5 were under one year of age, 52 under five; 1029 between five and sixty, and 162 over sixty years of age.

Another interesting point is the mortality among those of different nationalities. Of the decedents, 853 were French, and 330 Italian, the latter paying large tribute to the epidemic, the proportion being 5.70 per 1000, while for the French it was 2.93, and for all other foreigners 1.36 per 1000. Dr. Albenois's explanation of this high mortality among the Italians is, that they are, as a class, extremely poor, and engaged in the hardest and most repugnant work, receiving but small wages, at the same time having large families, and living in the most unhealthy sections, in close and crowded quarters, often deprived even of the necessaries of life, it is then not at all astonishing that they fall easy victims to the epidemic.

During the month there were attributed to diarrhœal diseases 272 deaths. The total number of deaths was 2478; and the annual death-rate 82.6 per 1000

Prof. Carl Wedl.—The Emperor of Austria has conferred the title of "Hofrath" upon Dr. Carl Wedl, Professor of Histology in the University of Vienna, in recognition of his long and useful services to science.

Obituary Record—Julius Cohnheim.—The closing days of the International Medical Congress were saddened by the announcement by Prof. Virchow, in the Section of Pathology, of the death from gouty nephritis, in Leipzig, on August 14th, of his distinguished pupil, Prof. Julius Cohnheim. A telegram of condolence was immediately sent to his widow by the Section.

Prof. Cohnheim was born in Demmin, in 1839, and studied medicine from 1856 to 1860 in Berlin, Würtzburg, Griefswald, and Prague. He commenced to practise in Berlin, but was appointed, in 1864, assistant to Prof. Virchow in the Pathological Institute, when he entered upon a new life. In 1868 he was appointed Ordinary Professor of Pathological Anatomy in Kiel. He soon left Kiel, however, to succeed Waldeyer in Breslau. His work here was probably the most brilliant and fruitful of his whole life; so much so, that he was called to the Pathological Institute, in Leipzig, on the occurrence of the first vacancy. His name will chiefly be remembered for his contributions to the doctrine of inflammation. His discovery of the migration of the white blood-corpuscles through the walls of the capillaries in inflammation is his chief title to fame. It is too early, says the *Deutsche medicinische Wochenschrift*, to estimate the great influence of his work, and we can only know that in his death practical pathology has sustained an irreparable loss, even though in his "Vorlesungen" he has left a work, for him an enduring monument, which combines physiology and pathology to one extent never before attained. Few more important truths have been formulated in medicine than Cohnheim's, "without bloodvessels no inflammation is possible."

——On September 6th, in this city, aged seventy-seven years, Robert Empie Rogers, Emeritus Professor of Chemistry in the Jefferson Medical College.

Dr. Rogers received his medical education at the University of Pennsylvania, and graduated in 1836. From 1844 to 1852 he held the Chair of Chemistry in the University of Virginia, and from 1852 to 1877 the same Chair in the University of Pennsylvania, and for the last seven years he has occupied the Chair of Chemistry in the Jefferson Medical College.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 2 TO SEPTEMBER 9, 1884.

Byrne, Chares C., *Major and Surgeon.*—Relieved from duty in Department of California, and to report in person to the Commanding General, Department of the Platte, for assignment to duty.—*S. O. 207, A. G. O.*, September 3, 1884.

Town, F. L., *Major and Surgeon.*—Relieved from duty in Department of the Columbia, and to report in person to Commanding General, Department of Texas, for assignment to duty.—*S. O. 207, C. S., A. G. O.* Granted leave of absence for twenty-five days.—*S. O. 127, Department of the Columbia*, August 25, 1884.

Havard, Valery, *Captain and Assistant Surgeon.*—Relieved from duty in the Department of Texas, and to report in person to the Commanding General, Department of the East, for assignment to duty.—*S. O. 207, C. S., A. G. O.*

Hall, Wm. R., *Captain and Assistant Surgeon.*—Relieved from duty in Department of Texas, and to report in person, on October 1, 1884, to the Superintendent-General of Recruiting Service, in New York City, for duty at David's Island, N. Y., relieving Assistant Surgeon M. E. Taylor from duty at that station.—*S. O. 207, C. S., A. G. O.*

Hopkins, Wm. E., *First Lieutenant and Assistant Surgeon.*—The leave of absence granted him in S. O. 67, August 7, 1884, Department of Arizona, is extended one month.—*S. O. 204, A. G. O.*, August 30, 1884.

ORIGINAL LECTURES.

A COURSE OF LECTURES ON DERMATOLOGY.

Delivered at the University of Pennsylvania during the Session of 1883-1884.

BY LOUIS A. DUHRING, M.D.,

PROFESSOR OF DERMATOLOGY IN THE UNIVERSITY.

(Reported by Henry Wile, M.D.)

LECTURE VII.

SYPHILODERMA; LEPRA; FRAMBŒSIA; PELLAGRA; EPITHELIAL CANCER; SARCOMA; LYMPHANGIOMA; MYOMA; DERMATALGIA; PRURITUS.

SYPHILIS OF THE SKIN, or syphilis cutanea, includes the various manifestations upon the skin due to syphilis. The syphilodermata occur in a manifold variety of lesions, in more numerous forms even than eczema, and the statement of some authorities, that there is scarcely any form of cutaneous lesion which syphilis may not assume, is suggestive.

General symptoms are, as a rule, absent, though slight fever, malaise and languor are sometimes met with. Other symptoms usually concomitant, are enlargement of the lymphatic glands, angina, alopecia and the occurrence of mucous patches. Syphilis attacks no particular region, although the different forms of eruption show preference for certain localities. Symmetry is a characteristic of the earlier eruptions; irregularity in distribution of the later forms.

The lesions of cutaneous syphilis are noted for their multiformity, almost all of the forms common to other cutaneous diseases being liable to appear, the papule and pustule, however, being the most frequent. Polymorphism is commoner in the earlier than in the later eruptions. The configuration is also peculiar, the earlier lesions being rounded, while the later assume an annular, crescentic or serpiginous form. The color varies with the age, complexion, and stage of the disease. Early lesions are first of a pinkish or dull-reddish hue, usually passing through varied tints to a violaceous, coppery or brownish-red color. Older lesions, especially papules and tubercles, often have a deep-red, cold, non-inflammatory look.

The course of the disease is usually slow; especially is this the case with the later forms. Relapses are common. Subjective symptoms are, as a rule, absent; pain is, however, sometimes present with ulcerative lesions. Itching occasionally accompanies the small papular and pustular syphilodermata.

Syphiloderma erythematosum, or macular syphiloderm, consists of rounded or ovoidal macules, pea- to finger-nail-sized, ill-defined, faint or marked, bright or dull pinkish or violaceous, often presenting a mottled or marbled appearance. Later, the lesions grow darker, assuming a dirty-yellowish, dusky-brownish or coppery color, and then disappear. They are generally numerous, and appear first upon the trunk, abdomen and thorax, then upon the flexor surfaces of the limbs, and sometimes upon the face. The eruption has no regular distribution. It is the earliest syphiloderm, and appears in from six to ten weeks after the initial lesion, with or without malaise or other general symptoms or signs of syphilis. Its development is, as a rule, slow, requiring one to two weeks, though it may be rapid, coming out over night or after a hot bath. Its duration varies from a few weeks to several months. It must be distinguished from measles, rötheln, urticaria, and medicinal eruptions—as from quinine and copaiba; also from tinea versicolor.

Syphiloderma papulosum is an eruption in which the lesions vary in size and shape, generally being the size of a millet-seed, pea or small bean, acuminate or flat, discrete or confluent. On account of this variation in size, the division into the small and large papular syphiloderm is proper, by which cases can be more easily and precisely classified.

The *small papular syphiloderm*, also called the miliary papular syphiloderm, occurs in the form of millet-seed sized, rounded or acuminate, generally profuse lesions, which are elevated, firm or solid, disseminated or grouped, and of a bright or dull red color. The eruption is usually well marked; occurring as an acute process it may appear in a few days. It may be an early or a late manifestation, showing itself at any time between the second and twelfth month; when late, it is generally in conjunction with the large papular syphiloderm. It is mostly seen on the trunk, upper extremities and thighs, and is more common in debilitated subjects and in women than in men, and runs a chronic course, leaving pigment stains. In the matter of diagnosis, it is to be distinguished from keratosis pilaris, from papular eczema, and from psoriasis punctata.

The *large papular syphiloderm*, also called the lenticular papular syphiloderm, consists of pea to bean-sized flat, rounded or ovoidal, elevated, firm and circumscribed, pale or dull red lesions. They are usually profuse and are found more abundantly in certain localities, as on the forehead, nape of the neck, back, and flexor surfaces of the extremities. It is one of the commonest of the syphilitic eruptions, and is an early manifestation, closely following the erythema, and is often rebellious to treatment. Location influences these lesions and effects certain modifications in them. When arising on the mucous membrane of the mouth or in the axilla, groin, about the genitalia or beneath the mammæ in women, where the skin on account of opposing surfaces is kept moist by excessive perspiration, the epidermis becomes macerated and the lesions are then called *moist papules*, or *flat condylomata*. Sometimes there is an excessive proliferation of the rete cells giving rise to papillary or warty growths—occasioning the *hypertrophic* or *vegetating syphiloderm*. On the other

hand, the papule may undergo the opposite change, giving rise to the *papulo-squamous syphiloderm*, in which the lesions are for the most part grouped, forming patches, and covered with layers of thin, grayish, more or less adherent scales. The regions thus attacked are usually the palms and soles, and the character of the lesions is due to the peculiar anatomy of the skin in those regions, the epidermis being very thick. The eruptions are also known as the *palmar* and *plantar syphiloderms*. They are generally symmetrical, occurring usually in the centre of the palms or soles, the lesions for the most part assuming a crescentic shape with elevated edges. When unilateral, it is generally a late manifestation. It is liable to be mistaken for eczema, psoriasis and callosity, but the history and development of the lesions, together with the shape and sharp definition, are usually sufficient to establish the diagnosis.

Syphiloderma vesiculosum is an exceedingly rare form of cutaneous syphilis, there being but few marked cases on record. The lesions generally resemble those of varicella, and usually appear about the face and genitalia, where the skin is thin.

Syphiloderma pigmentosum (syphilitic chloasma) is very rare in this country, but more common in France. It occurs chiefly upon the neck, mostly of women with delicate, thin skins, and, usually, in the second year after infection. The lesions are pea-sized, and consist of simple, pale-brownish, pigmentary deposits.

Syphiloderma pustulosum constitutes an important class, and is divided into varieties according to the size and general characters of the lesions.

The *small acuminated pustular syphiloderm* is similar in appearance to the miliary papular syphiloderm, except that the lesions are pustules, and may often be an advanced stage of the latter. The lesions consist of small, pin-head sized, rounded or pointed pustules situated on a red elevated base. They are always abundant, occurring as discrete or confluent lesions, forming large groups, circles or crescentic patches. Their favorite seats are the arms, thighs, chest, and back. Sooner or later the puriform contents dry into yellowish crusts, which dropping off are followed by pigmentary stains. This eruption may occur as early as the second or third month, and in this case usually disappears rapidly.

The *large acuminated pustular syphiloderm* may resemble acne very closely, and is sometimes also difficult to distinguish from variola. It is acute or chronic, usually the former, and accompanied by pain, languor and fever. It attacks the face, scalp and trunk, and also the upper extremities and the thighs. It is a somewhat rare manifestation, generally occurs early, and is amenable to treatment.

The *small flat pustular syphiloderm*, or impetigo-form syphiloderm, is also a rare variety, looking not unlike pustular eczema. The pustules occur in patches for the most part upon the face around the nose and mouth; also about the genitalia, the lesions soon rupturing, forming yellowish, greenish or brownish crusts.

The *large flat pustular syphiloderm*, or ecthyma-form syphiloderm, consists of finger-nail sized flat pustules upon a red base, which soon form crusts. There are two varieties, the superficial and deep-seated. In the former the flat, yellowish-brown crusts cover a superficial, freely secreting ulcer, and the lesions generally appear after the sixth month, and mostly upon the back, shoulders and extremities. The deep-seated variety, known as *rupia*, is a late manifestation, and possesses a malignant character. The crusts are thick, stratified, hard, of a greenish or blackish color, and cover a sharply defined, excavated ulcer, secreting a copious, greenish, puriform fluid.

Syphiloderma tuberculosum is usually a late manifestation, and is seen more frequently than any other eruption; occurring one, five, ten or twenty years after the initial lesion. The lesions vary in size from a small to a large pea, or are in the form of flat infiltrations, of a bright or usually dark-red, coppery, smoky hue; single, or more commonly multiple, disseminated, or grouped, or arranged in circles, segments of circles, or serpiginous tracts. The course is slow; they may, for a time, remain without undergoing any change; on the other hand, they may go on to ulceration or absorption. There are usually no subjective symptoms. When in the state of ulceration, papillary or cauliflower growths may spring up from the surface. The tubercular syphiloderm is to be diagnosticated from lupus vulgaris, cancer, and lepra, and the characteristic points to be remembered are the sharp, punched-out nature of the ulcer, its deeply infiltrated and raised border, and relatively rapid development.

Syphiloderma gummatosum, gumma or syphiloma, begins as a small, pea-sized, soft, elastic, colorless or pinkish subcutaneous tumor, growing slowly to the size of a hazel-nut or walnut. It has a tendency in time to break down and ulcerate with great destruction of tissue. Gummata rarely exist in numbers, usually but one or two occur, and most commonly in debilitated individuals, five or ten years after the initial lesion, though exceptionally as early as the first or second year of the disease. It is to be diagnosticated from simple abscess, furuncle, lymphatic gland, cancer, and fibrous and fatty tumor. It heals by absorption, or ulcerates and leaves an insignificant scar compared with the amount of ulceration.

Syphiloderma bullosum, a rare, late manifestation, consisting in the formation of blebs, which generally become puriform, and dry, and form large stratified crusts. Its presence indicates a greatly depressed state of the system.

Syphiloderma hæreditarium infantile.—The child may come into the world apparently healthy or with cutaneous manifestations, the former usually being the case. A month or six weeks after birth, lesions appear, attended with coryza and snuffles, consisting of erythema, maculo-papules, papules, blebs, or a mixture of these, generally occupying the thighs, buttocks, genitals, palms and soles, together with mucous patches. The bullous syphiloderm is, as a rule, present at birth, and consists of variously sized blebs, occurring most frequently about the hands and feet. These lesions soon rupture, and may give rise to ulceration.

The pathology of the syphilitic papule or tubercle shows it to be a neoplasm, composed of small, round, lymphoid cells, packed together, forming an infiltration resembling that of lupus vulgaris. The cell-deposit is most marked around and in the immediate neighborhood of the bloodvessels; it occupies more or less all the layers of skin below the horny layer, and is sharply circumscribed.

Respecting treatment, mercury and iodide of potas-

sium are our most valuable remedies; and with them mainly the disease must be combated. They are administered in varying doses and in various combinations. When used together they constitute what is known as the "mixed treatment." Mercury, when used alone, may be administered by the mouth, by hypodermatic injection, or by inunction; in all cases salivation is to be avoided. The objections to the hypodermatic method, as introduced by Lewin, of Berlin, is that it is painful, and that patients generally object to its employment. Subcutaneous abscesses also often follow, and the procedure consumes too much time for the patient. The administration by the mouth is preferable to that by inunction, in that it avoids the staining of linen, takes up much less time, and, above all, in that the dose can be more accurately given. In the mixed treatment, the formula generally used is as follows:

℞.—Hydrargyri biniodidi, . . . gr. iss.
Potassii iodidi, ... ʒiij.
Syr. sars. co., ... fʒiv.—M.

Sig.—One teaspoonful, with water, thrice daily.

Local treatment of ulcerations may consist in the use of ointments of ammoniated mercury, one-half to one drachm to the ounce of lard; or ointment of the nitrate of mercury, one to two or four drachms to the ounce; or the oleate of mercury ointment, five to twenty per. cent. strength. A mercurial ointment is also valuable, and is almost exclusively used in the hospitals of Vienna.

Lepra, known also as leprosy and as elephantiasis græcorum, has of late received considerable attention in the journals. The disease in our country occurs not only on the coast of California among the Chinese, but also in Louisiana and in Minnesota, and in other States. It may be defined as an endemic, chronic, malignant, constitutional disease characterized specially by disease of the cutaneous, nerve and bone structures, resulting in anæsthesia, ulceration, necrosis, general atrophy, and deformity. Its invasion is usually slow and insidious, with premonitory symptoms of debility, nervous prostration, languor and the like. Persons sojourning in foreign countries for a time, as English soldiers in India, may thus contract the disease. Sooner or later blebs, macules, and pigmentary or tubercular lesions appear, together with nerve involvement and other symptoms.

Two forms of leprosy are recognized: tubercular and anæsthetic, which, however, may coexist.

Lepra tuberculosa is characterized by masses of infiltrations and tubercles preceded generally by an eruption of blebs, which are often the first manifestation. Macules then appear in the form of smooth, shining, erythematous patches, the condition being known as *lepra maculosa*. The lesions are of a yellowish or brownish color, present a brawny appearance, and usually involve the trunk and extensor surfaces of the extremities. The sensibility of the parts affected is markedly altered, there being first hyperæsthesia, then anæsthesia. The course of this variety is variable, sooner or later tubercles and prominent tumors begin to appear, giving rise to *lepra tuberosa*. The lesions are seated in the skin and subcutaneous tissue, are of a brownish or bronzed color, situated, for the most part, about the face, producing a striking appearance known as *leontiasis*, the features becoming distorted, and the skin thickened, swollen and infiltrated. It may also attack the mucous membrane of the mouth, pharynx, epiglottis, and larynx. Ulceration occurs commonly about the fingers and toes.

Lepra anæsthetica may appear with the tubercular form or alone. Blebs followed by a pigmentary deposit often precede the anæsthesia. Hyperæsthesia may also precede it, attended with pain and burning sensations. The macular patches are generally anæsthetic, so much so that a pin may sometimes be thrust into them without giving rise to pain. The skin and also the deeper structures become atrophied, while the fingers and toes become crooked, bent and mutilated, the ends often dropping off, giving rise to *lepra mutilans*.

The causes are obscure. The disease generally exists endemically, especially in certain countries, as along the shores of the Mediterranean Sea, Atlantic and Indian Oceans, also in Asia Minor, India, China, and in some of the islands of the Pacific Ocean, especially the Sandwich Islands. It is also met with in Norway, Greece, Spain and Sicily; and in Mexico, Central America, West Indies, Brazil, and sporadically in the United States. A case is reported which occurred near New York, the patient never having been outside of his native county, and in which there was no evidence of hereditary taint. As to the contagiousness of the disease authorities stand divided, and strong evidence is brought forward on both sides. It is probable that the disease is contagious in the sense that syphilis is contagious. It is hereditary, being handed down from generation to generation. It is a distinctive disease, and has no relation with syphilis. The cause seems to be intimately connected with climate, soil, food, and habits of the people.

As to its pathology, it is a cellular deposit, like that in lupus and in syphilitic new formations, being most marked around the thickened bloodvessels. It involves the nerves, and thus gives rise to pain and anæsthesia. In the diagnosis it is to be distinguished from lupus, syphilis, scrofula, vitiligo, and morphœa. The premonitory symptoms and constitutional disturbance, together with the history of the case, and the deep-seated pain or anæsthesia, are usually sufficient to mark the disease and to prevent any error in diagnosis. As to treatment, hygiene, change of climate, and regulation of diet are of the utmost importance. Alteratives such as iodide of potassium, quinine, iodine, and cod-liver oil are useful, also gurgun oil, chaulmoogra oil, and Hoang-Nan, the last three being used by the natives, and are supposed by some to exert a good influence upon the disease. Locally baths of sulphur and inunctions with various oils, as gurgun and chaulmoogra, are highly recommended.

Frambœsia, also called yaws and pian, is an endemic disease of the West Indies, Fiji and other islands, South America, and the coast of Africa. The eruption is accompanied by constitutional febrile symptoms, and is characterized by variously sized reddish papules and tubercles, resembling a strawberry or a currant, which soon ulcerate and break down.

Pellagra, or Lombardian leprosy, is an endemic

disease occurring mostly in the northern parts of Italy. The eruption, which is confined chiefly to those parts exposed to the sun, consists of a diffuse inflammatory redness ending in desquamation or the formation of vesicles and bullæ followed by crusts. The disease is accompanied by nervous prostration, melancholia, loss of mental power, and is said to be more common at certain times of the year. It is supposed by some to be caused by the ingestion of a certain ergot of rye or maize.

Epithelioma, epithelial cancer, or cancroid, may manifest itself in one of three varieties—superficial, deep-seated or papillary.

The superficial, known also as the flat variety, usually makes its appearance as one or more yellowish or reddish papular elevations, often starting in a sebaceous gland or wart. Sooner or later it breaks down, oozes, discharging a watery or bloody secretion, and becomes crusted. An ulcer now forms, crusted, and with a variable amount of induration, which later becomes marked and sometimes ring-like around the sore, or later even distinctly everted. The lesion may at first be small, the size of a pea, and later develop to the size of a silver dollar. A chronic form of this variety of cancer is known as *rodent ulcer*, occurring usually about the face, especially the upper half, more particularly the orbital region. It develops slowly, and may last from five to twenty years.

The deep-seated (known also as the infiltrating) variety generally begins as a firm, reddish tubercle in the skin, sometimes involving the subcutaneous tissue. It may start in a wart or nævus, and after a varying period of time, usually months, ulceration sets in. The lesion secretes a yellowish offensive fluid, its edges become infiltrated, and the whole process is attended with destruction of tissue, and frequently pain. The course of this variety of cancer may be slow or rapid.

The papillary variety occurs in the form of a papillary, warty, cauliflower-like growth, and often begins in a wart. The lesions, varying in size from a pea to a dollar, are raised, spongy, soft, dry or moist, crusted or covered with a viscid, sebaceous or bloody secretion. The common site of the disease is the face, especially about the mouth. It usually arises from an irritated point in the tissues, *e. g.*, excoriations from smoking a pipe, warts and nævi. It occurs more frequently in males than in females, and is most common after middle life, between the age of fifty and sixty.

Pathologically, it is an epithelial proliferation of a malignant type, the malignancy being variable. The cell of the new formation is of the squamous epithelial type, and the excessive development of the rete mucosum downwards into the corium in the form of tubular prolongations, gives rise on section to the numerous epithelial nests or pearly bodies, which are characteristic. This epithelial proliferation is accompanied by a subacute inflammatory process by which the tissue of the corium becomes the seat of a small round-cell infiltration, the whole being followed by subsequent degenerative changes. The disease begins in the normal squamous epithelium of the skin or mucous membrane. It is the least malignant variety of cancer.

Epithelioma must be differentiated from syphilitic tubercles and ulcerations, lupus, and common wart. The development of syphilitic lesions is more rapid than cancer, and the secretion in the former is more profuse. The edges of the cancerous lesion are everted, and the surrounding tissue is more or less infiltrated, while in syphilis the induration ends abruptly. In the former there is also pain, which is, as a rule, absent in the latter. To distinguish epithelioma from simple wart, the age of the patient, the mode of growth and course of the disease are necessary to support the diagnosis. From lupus vulgaris it is diagnosticated by it attacking the middle-aged or elderly, by its appearance, and that it occurs generally as a single lesion. Lupus is a disease of childhood and usually invades several parts of the body. The cancerous ulcer secretes a pale or bloody, viscid, often offensive fluid, while the secretion from the lupus ulcer is puriform and inoffensive.

The treatment of this disease consists of complete removal of the growth by means of the knife, curette, caustics or galvano-cautery, or in its destruction by electrolysis; one of these means is to be employed, according to the region, location, and size of the lesion. The superficial variety may in most cases be successfully treated by a thorough application of caustic potash, destroying not only the growth, but the bordering healthy tissue. The pain usually subsides immediately after the application; if not, it can be relieved by bathing the part with dilute acetic acid. After cauterization some mild dressing, as of olive oil, may be used, and in a week or two the blackish eschar will fall off leaving a granulating surface which, in favorable cases, soon heals over leaving a scar. Other caustics, as arsenic with powdered acacia, equal parts, made in the form of a paste, or pyrogallic acid in the form of an ointment, one or two drachms to the ounce, are also useful in some cases. The treatment with the curette, or scraping-spoon, is of great value in the superficial variety, and should precede the use of caustics. In the deep-seated variety the most satisfactory treatment is that by the knife. It is also the best resort when repeated cauterizations have failed to arrest the development of the process. The prognosis should always be guarded, as relapses are common.

Sarcoma of the skin consists of pea- or bean-sized, pigmented or non-pigmented, discrete, smooth, firm and elastic, reddish, violaceous or brownish tumors. The multiple pigmented variety generally occurs on the soles and backs of the feet, then upon the hands, the lesions being of a brownish, bluish or blackish color. It generally proves fatal, usually in a few years. The term *inflammatory fungoid neoplasm* has been used to express a rare form of sarcomatous disease, and occurs in variously sized, flat or oval, smooth or scaly, pale pinkish, reddish or violaceous, tubercular or fungoid tumors. The lesions may develop slowly or rapidly, the process running a variable course, tending to terminate fatally.

Lymphangioma of the skin is characterized by multiple, pea-sized brownish or yellowish, somewhat translucent discrete, glistening, smooth, flat tumors, found mostly on the trunk. They grow paler on pressure, and do not seem to the touch to be sharply circumscribed.

Neuroma of the skin is characterized by various sized fibrous tubercles, containing new nerve elements, having their seat primarily in the corium, whose development is attended by violent paroxysmal pains.

Myoma of the skin consists of tumors composed of smooth muscular fibres. They are of a pale, rose or dull-red color, rounded or oval, pea- and bean-sized, slightly raised, solitary or multiple, and are not to be confounded with lymphangioma nor with molluscum fibrosum.

Dermatalgia is characterized by distinct localized neuralgic pain in the skin or with a morbidly sensitive condition of the integument. The symptoms are varying, and the pain may be general or local—usually the latter, slight or severe. The affection is often associated with rheumatism, and may be symptomatic of organic disease of the central nervous system. The treatment depends upon the variety, whether symptomatic or idiopathic. In the former, the general condition demands attention; and in the latter, local application of the galvanic current, blisters and aconite plaster may be tried.

Pruritus is a functional cutaneous disorder, characterized by itching without structural change. The sensation is variously described as a feeling of irritation, formication or tingling. The disease is a common one, and may occur at any age. Occurring in elderly individuals, it constitutes so-called *pruritus senilis*. The itching, as a rule, is paroxysmal, and is worse at night. The disease may be universal or local, usually the latter, occurring frequently about the anus, scrotum and vulva, where it may be most distressing. The causes are varied; in children, pruritus ani may be caused by worms in the bowel; in females, it may occur in connection with gestation, irregular menstruation, hysteria, organic disorders of the uterus and ovaries. It may also be associated with diseases of the kidney, albuminuria, diabetes mellitus, hepatic diseases, jaundice, also with diseases of the nervous system and genito-urinary tract. Pathologically, it is a disease of purely functional character, usually the result of reflex nervous action.

The diagnosis offers no difficulty, as the surface of the skin presents none but secondary lesions, produced by scratching or irritants. It may be confounded with pediculosis, but in the latter disease the secondary lesions are more extensive. With prurigo it has nothing in common except itching; in the former disease there is a distinct primary papular eruption. In the erythematous and papular varieties of eczema the primary lesions are usually characteristic. The disease demands both constitutional and local measures according to the cause, which should always be determined. The bowels should be regulated; if constipation exist, saline laxatives are indicated; if there be any dyspepsia, the diet must be regulated, and all indigestible articles of food prohibited. Where there is general debility, tonics, as quinine and strychnine, and belladonna may be prescribed; and where the kidneys are at fault, or the disease is secondary to jaundice, the alkalies may be used with advantage. Sulphur and its preparations, especially the hyposulphite of sodium, are sometimes useful. External treatment is always demanded. Hot water applications and alkaline baths and the tarry alkaline lotions are of service. Lotions are valuable containing carbolic acid and thymol, simple or as follows:

℞.—Acidi carbolici, . . . fʒss to fʒj.
Potassæ, ... fʒss.
Aquæ, ... fʒiv.—M.
Sig.—Use as a lotion, diluted with water.

One containing corrosive sublimate may also be given:

℞.—Hydrargyri bichloridi, . . . gr. viij
Alcoholis, ... fʒiv.
Aquæ, ... fʒiijss.—M.
Sig.—Use as a lotion, diluted.

Essence of peppermint and glycerine, equal parts; dilute hydrocyanic acid, one to four drachms to the pint of water; and hyposulphite of sodium, one drachm to the ounce, may prove useful. Of the numerous formulæ, the following may also be mentioned:

℞.—Boracis, ... ʒij.
Glycerinæ, ... fʒss.
Spts. camphoræ, ... fʒj.
Aquæ rosæ, ... fʒvjss.—M.
Sig.—Lotion.

℞.—Fol. belladonnæ,
Fol. hyoscyami, . . . āā ʒij.
Fol. aconiti, ... ʒss.
Acidi acetici, ... fʒj.—M.
Sig.—Lotion, to be diluted with water, one drachm to the ounce.

℞.—Camphoræ,
Chloralis hydratis, . . . āā ʒj.
Ungt. aquæ rosæ, ... ʒj.
M. ft. ungt.
Sig.—Apply several times daily.

Pruritus hiemalis is a name employed to designate an irritable condition of the skin accompanied by itching and occurring during the winter months. The affection may occur in different degrees of severity and is usually most severe at night. As the spring approaches, the disease gradually disappears, but generally reappears the next autumn. It may attack any part of the body, although it is found most frequently upon the lower extremities. Where it has existed for some time, excoriations may result from scratching. The treatment is palliative, and consists of vapor baths and the use of the various emollient ointments and lotions referred to.

A CASE OF SARCOMA OF THE SKIN AND CELLULAR TISSUE ABOUT THE ANKLE, WITH REMARKS.[1]

By FRANCIS J. SHEPHERD, M.D., C.M.,
Professor of Anatomy in McGill University, Surgeon to the Montreal General Hospital.

The clinical interest of the following case furnishes me with a sufficient excuse for its publication.

Edward M., aged eighteen, native of Switzerland, a delicate-looking youth, came under my care at the Montreal General Hospital in April last, suffering from an ulcerated swelling about the left ankle. No history of struma or rheumatism in his family, and he himself has, with the exception of the present disease, always been healthy.

[1] Read before the Montreal Medico-Chirurgical Society, June 27, 1884.

He gave the following history of his case:

Some six years ago, while running, he fell and injured his left ankle-joint. The doctor told him it was dislocated, but after six weeks' rest the pain disappeared, and he could walk as well as ever; the swelling about the joint due to the injury, however, never entirely disappeared. A year subsequent to the above-described accident the ankle again became painful, and the swelling and tension markedly increased. His doctor, thinking an abscess had formed, opened the swelling, but failed to get pus, blood only escaping from the incision; this incision has never entirely healed, but ever since has remained open as a sinus, discharging a thin sanious pus. Three years ago he was kicked by a horse on the affected ankle; this caused an aggravation of the pain and swelling. The ankle-joint itself since the first accident has apparently never been affected, and its movements have always been free and comparatively painless, but the swelling on the inner side has been slowly increasing in size, and at different points sinuses, which discharge a thin pus, have formed.

When I first saw him, the parts about the inner side of the left ankle-joint were of a shiny, dusky-red color, and considerably swollen. The swelling extended from a point several inches above the tip of the internal malleolus to below the tarsal joint, it also extended laterally to the sole of the foot, half way across the instep, here the skin over the swelling was quite normal. There was also fulness over the tendo Achillis and the parts behind the internal malleolus. Near the edge of the swelling were several reddish tuberculous nodules the size of large peas. There were also a number of sinuses in the upper part of the swelling, and near the centre a spot of ulceration the size of a ten-cent piece. The swelling, which was not at all well defined, on pressure gave a sense of fluctuation, or rather felt like a mass of some semifluid substance. During pressure no pus exuded from any of the sinuses. There was but little pain in the part, and patient only complained when his foot was handled a little roughly. On probing the sinuses carefully no necrosed or carious bone could be felt.

Not feeling perfectly sure of the diagnosis, but supposing from the semi-elastic sensation conveyed by pressure, and also the history of the case and the evident healthiness of the ankle-joint itself, that the disease was some form of neoplasm, I decided to place the lad under ether and carefully explore the parts affected. This I did after observing the case for a day or two. I made a free incision in the long axis of the swelling over the inner malleolus, and after cutting through very thick infiltrated skin, came upon a lot of tissue looking like granulation-tissue; this substance appeared to be in pockets, and could be squeezed out by using some force. The lining membrane of these pockets was smooth and shiny. I cut through the whole thickness of the swelling and was still superficial to the annular ligament of the ankle and the tendons which pass under it; the movements of the tendons were in no way interfered with. Feeling sure I had to do with a new growth, I sent some of the substance taken from the pockets to my friend Dr. Wilkins, for microscopical examination, and he pronounced it a very good example of round-cell sarcoma.

On consultation with my colleagues, amputation of the leg was decided on. The lad and his friends, on learning the serious nature of the disease and the danger of delay, at once consented to the amputation.

I omitted to mention that the glands in the groin were much enlarged, one, below Poupart's ligament, had increased to the size of a pigeon's egg. I looked upon this condition of the glands as purely inflammatory, knowing the rarity with which sarcomatous tumors secondarily affect the glands, and also knowing that they had been enlarged ever since the first accident. In the interval between the making of the exploratory incision and the amputation, the swelling had slowly increased in size and extent, and the incision had rapidly filled up with coarse granulation-tissue.

I amputated the leg on May 17th at some distance above the disease, dressing the stump, as I usually do in amputations, with iodoform and pads of sublimated jute. In this case I made use of decalcified bone drains, which, owing to their collapse, had to be replaced on the second day by rubber tubes. From this time the case progressed favorably, the temperature after the third day never reaching 99°, and in less than three weeks' time, with three dressings, the wound was practically healed. The enlarged glands below Poupart's ligament gradually diminished in size; and when last seen a few days ago, the lad was in good condition, felt well and strong, and the enlarged glands had almost entirely disappeared. Whether or not he will have a return of the tumor in some other part remains for time to show. Owing to the long duration of the growth and its being of the most malignant variety of the sarcomata, it is possible that infection may have been conveyed to other parts.

This case is instructive chiefly on account of the difficulties it presented for diagnosis. In the first place, the situation was an unusual one for a sarcoma; again, it resembled more some chronic form of inflammation connected with periosteal or bone disease than a sarcomatous tumor and it was only after a careful exploratory incision and a microscopical examination that its true nature was made out. I need not dwell upon the importance to the patient of a correct diagnosis in these cases, for sarcoma, and especially the round-cell variety, unless removed, is a fatal malady. The patient before coming under my care had been treated for some months on the supposition that his affection was of an inflammatory nature. What led me to suspect a new growth was the existence of apparent fluctuation with the presence of numerous sinuses, the freedom from pain on movement of the joint and the absence of any carious or necrosed bone.

The long duration of the tumor, and the fact that it can be directly traced to traumatism as its cause, add further interest to the case. Cases have lately been reported by Mr. Barwell and others in which injury was followed by an acute and rapidly growing sarcoma; this is comparatively rare, but slowly grow-

ing sarcomata not infrequently follow injuries, a fact which was pointed out by Billroth many year ago.

It is of rare occurrence that the skin of the parts about the foot is affected with sarcoma; the more common forms of sarcoma of the lower extremity being connected with bone itself or the parts in connection with bone. When the skin is the seat of a sarcomatous tumor it is of the spindle-cell variety, as a rule, round-cell sarcoma being very rarely seen in connection with the skin.

Prof. Markoe, in THE MEDICAL NEWS of April 26, 1884, reported a series of cases of what he calls "Sarcoma of the Sheaths of Tendons about the Foot." His cases closely resemble that which I have just narrated to this Society. The skin, however, was not involved in Dr. Markoe's cases, the disease being confined to the parts immediately beneath. It seems to me that Dr. Markoe's description of his cases hardly bears out the idea put forth by him that the tumors were connected with the sheaths of the tendons.

One thing is certain, that these sarcomatous tumors about the foot are of rare occurrence, and if their true nature is not ascertained in time the life of the patient will be endangered, for though at first apparently innocent, sooner or later they develop the greatest malignity.

LAPAROTOMY, WITH REMOVAL OF A CYSTO-FIBROMA OF THE UTERUS AND A SMALL CYST OF BROAD LIGAMENT, TOGETHER WITH BOTH OVARIES AND FALLOPIAN TUBES.

BY MANNING SIMONS, M.D.,
OF CHARLESTON, SOUTH CAROLINA.

Miss X., aged 29, governess, American, consulted me in September, 1883, in relation to an abdominal tumor. She had always enjoyed good health and had been accustomed to an active life. She contracted malarial fever in the fall of 1882. She came to Charleston for treatment on account of the chills and fever into which her acute attack had degenerated. At that time she was pale and anæmic, but soon recovered her ordinary health after removal from the malarious region in which she had been living. I did not see her again until September, 1883, when she returned to Charleston to seek advice on account of the tumor.

She stated that in the summer of 1882 she received a severe blow on her abdomen by falling against a table. Beyond the pain and soreness for a few days, she attached no importance to this accident. In February, 1883, she observed a lump in the right side of the abdomen, which was hard but movable. She suffered intense pain in the abdomen, accompanied by nausea and a burning sensation. This pain was increased by stooping to lift anything, and she was very much fatigued by even a short walk.

About the last of April she noticed that the "lump" had shifted its position, appearing on the left side, accompanied by a good deal of soreness and pain. About this time her left leg began to swell and there was enlargement of the glands of the groin on the same side. This œdematous condition of the limb disappeared and returned from time to time.

In June the tumor assumed a position in the middle line of the abdomen and gave no pain or inconvenience except by pressure upon the bladder. There was no menorrhagia, but with the first appearance of the tumor the menstrual period was prolonged for two or three days beyond the usual time. She had, however, since that time been very regular both as to time and quantity of the flow.

In September, when she consulted me, I found a tumor which occupied the abdomen in the position and to about the extent of a pregnant uterus at seven months, reaching up to the umbilicus, completely filling the abdomen below that point and passing below the brim of the pelvis. The tumor had a perfectly solid feeling, and but for this might very readily have been mistaken for the pregnant uterus, which it closely resembled in shape. It was perfectly smooth. On vaginal examination the cervix was found to be that of a virgin, but the tumor could not be reached. By the bimanual method, the uterus was slightly moved by movement of the tumor. By rectal examination the uterus could be detected pressed downwards, backwards, and to the right side. For obvious reasons I did not explore the uterus with the sound.

After several examinations I became satisfied that there was a tumor, almost, if not completely solid, and probably connected with the uterus. From the nature of the case this connection could not be decided upon until the sound had been employed, and under the circumstances I determined to have a consultation before it was used. Prof. R. A. Kinloch having been called in, we passed the sound into the uterus, and it entered about three and a half inches, and to the right, taking the course indicated by the rectal examination as the position occupied by the uterus. On moving the tumor the handle of the sound could scarcely be said to deviate from its position to the right or left. We decided to leave the case, undetermined as to diagnosis because of some of its features, until another meeting, which should be held after the next menstrual period. During the next menstrual period I made an examination with the speculum, and saw the discharge issuing from the os, and in this way eliminated to some extent one of the elements of difficulty in the way of confirming a diagnosis. In February we made another examination, and on this occasion again passed the sound, with the same result as on the previous occasion.

In the meantime the tumor had increased much in size and its pressure-effects had become very painful and distressing to the patient, rendering it almost impossible for her to walk but a short distance, by reason of the weight and interference with respiration. She lost weight rapidly, and her face presented a distressed, pinched, and anxious expression. Our diagnosis was fibro-cystic tumor, connected closely with the uterus. It was determined to give her the benefit of an operation, which should be exploratory in its nature, but if there should be any reasonable prospect of removing the tumor with or without it

connections, with a chance of saving life, the operation was to be completed. My patient was removed to the St. Francis Xavier Infirmary, a new hospital recently erected in the western portion of the city, in full view of the Ashley River, and to a great degree isolated from other buildings. She was admitted on April 1st, one week before the day fixed upon for the operation, and carefully prepared for the ordeal by daily warm baths and frictions of the skin, regulation of the bowels, and a selected diet.

The operation was performed on April 8th, twenty days after the preceding menstrual period, with the assistance of Drs. R. A. Kinloch, Wm. H. Huger, W. C. Ravenel, P. Gourdin DeSaussure, and John L. Dawson, Jr. There were no spectators, and but five assistants, who carefully disinfected their hands.

Twenty minutes before the administration of the anæsthetic a hypodermatic injection of atropiæ sulph. gr. $\frac{1}{150}$, and morphiæ sulph. gr. $\frac{1}{4}$, was administered. The anæsthesia was first accomplished with chloroform and continued with ether.

Operation. An incision was made in the median line between the umbilicus and pubis, four inches in length, and the parts successively divided until the transversalis fascia was cut through; there was then exposed to view the subperitoneal tissue loaded with fat, which was removed piecemeal with scissors.

At this stage attention was devoted to the arresting of hemorrhage, which was very free. The peritoneum was then opened, no ascitic fluid escaped, and the tumor brought into view. It was of a white, pearly color, and solid to the touch except at one point, which gave an indistinct but delusive sensation of fluctuation. The sound was swept around and no parietal adhesions discovered. The patient was turned upon her right side and a trocar of small size was introduced into the tumor, giving in its passage the feeling of perfect solidity and density. Nothing save a little blood escaped from the canula. Coursing over the surface of the tumor were large vessels with very friable walls, which became ruptured in handling the tumor, and from these there was an active hemorrhage which could not be restrained either by forceps or ligature. The abdominal incision was rapidly extended with scissors, downwards to the pubis and upwards to the left of the umbilicus, to about two inches above the latter. The tumor was then lifted with difficulty out of the abdomen, the edges of the abdominal wound being as soon as possible covered with soft cloths wrung out in a warm solution of carbolic acid to prevent the passage of blood into the cavity, as well as to obviate the loss of temperature. It was found that the tumor was connected with the uterus at its upper border and to the left side by a pedicle about one and a half inches in length and two and a half inches in thickness. There were two considerable adhesions of the omentum to the tumor, and another adhesion apparently of the ascending colon. These adherent structures were tied, peeled off from the tumor, and dropped into the abdominal cavity. The pedicle was transfixed near the uterus by a long steel pin, and below it was placed a solid rubber cord which was tied in tension, effectually constricting the parts. The tumor was then ablated, no hemorrhage occurring from the stump. The pedicle was again transfixed below the rubber cord, with a needle armed with a double silk ligature, and tied in two portions. The ligature was next passed around the whole stump, including both halves, before it was finally secured.

The elastic cord was now removed and a wedge-shaped piece taken from the centre of the stump, leaving two lateral flaps. The effort was at the same time made to preserve as much of the peritoneal covering as possible, by which to invest the flaps. These flaps were then brought together with an uninterrupted suture of fine silk. This being accomplished, it was discovered that there was some subperitoneal hemorrhage coming from the track of the ligature surrounding the pedicle. It therefore became necessary to inclose the stump with another ligature between the uterus and the first ligature. This was a difficult matter, as there was now no space left on the pedicle, and this ligature had to be put upon the uterus itself.

To accomplish this a single silk thread was used, and to keep it in place (for the tendency was for it to slip into the track of the main ligature), as it encroached considerably upon the uterus, at the suggestion of Dr. Kinloch, I took a series of superficial stitches in the uterine tissue about three-fourths of an inch apart, until the stump was completely surrounded like the mouth of a purse. When this ligature was drawn close the hemorrhage ceased. This fine ligature was cut short, as was the main one, and the uterus dropped into the cavity.

The ovaries were then examined; both were found with beginning cystic disease, and in size equal to a large fowl's egg. These, together with the Fallopian tubes, were removed, their connections having been tied with fine silk ligatures. In connection with the broad ligament of the right side was found a small cyst which was likewise included in a ligature and removed.

The abdominal cavity was carefully sponged, and this process was continued until the sponges were returned unstained. The abdominal wound was closed with nine silver sutures passed one inch from the edge of the incision, the peritoneum being carefully included to the same extent. Before these sutures were passed, a flat soft sponge was interposed between the abdominal wound and the intestines, to intercept any blood which should escape from the punctures. At the lower angle of the wound a Thomas double-current rubber drainage-tube was introduced to the bottom of Douglas's cul-de-sac. Through the rubber tubing attached to the arms of the drainage-tube, with a Davidson's syringe the abdominal cavity was freely washed out with a warm one to forty solution of carbolic acid until the returning fluid was clear. A portion of this fluid was allowed to remain in the cavity. Seven superficial sutures of silk were introduced in the spaces between the deep sutures. At this stage an annoying hemorrhage occurred from a superficial vessel in the abdominal incision which gave some trouble. This being controlled, the incision was dusted with iodoform, and especially around the tube at the inferior angle; over this was placed borated cotton, and the whole dressing kept in place with a flannel bandage. The operation ex-

tended over an hour, but much of this time was consumed in arresting hemorrhage before the abdominal cavity was opened.

The tumor weighed seven pounds and measured in its greatest circumference 25½ inches; in its transverse circumference 20½ inches, and in its vertical circumference 22½ inches. It was of dense fibrous structure, giving the sensation of cartilage under the knife. It contained two small cysts; one of the size of a fowl's egg near the centre, the other at the periphery was the size of a goose's egg.

The patient reacted promptly after the operation; the temperature being 99° at 3 P. M., one hour and a half after she was put to bed. Nausea and vomiting were urgent for forty-eight hours. During the first twenty-four hours absolutely no nourishment was given, and nothing save occasionally a small piece of ice to allay thirst. On the evening of the second day milk and lime-water were administered every hour in teaspoonful doses. Menstruation appeared on the second day. On the fourth day there was hemorrhage from the superficial wound. The dressings were changed and the wound dusted with iodoform. The drainage-tube was also removed, as up to this time there had been no discharge through it. A tent was placed in the track occupied by the tube.

On the sixth day the patient took beef-tea with relish; up to this time she had only been allowed milk and lime-water. The wound was healed except at the lower angle. Removed the tent, which had some bloody matter upon it, but there was no unpleasant odor. No discharge followed the tent. On the seventh day as there was some tendency to sweating, the abdominal cavity was washed out with a solution of common salt carbolized; ʒj of salt, ʒijss of carbolic acid to the quart of water. With the first flow of the solution some blood-tinged matter returned immediately from the track of the drainage-tube.

It was evident that this track was separated from the general cavity of the peritoneum by plastic deposit. On the eighth day the nine silver sutures were removed and adhesive strips were applied to secure the line of incision from strain. The original track of the drainage-tube was washed out each day from this time until the fifteenth day, when it was omitted because the part had become almost entirely filled up with granulations; the discharge amounted to very little and was pure and clear. On the evening of the eighth day ordered calomel gr. jss and white sugar gr. xx at bedtime. On the ninth day administered ʒij castor oil, which operated four times freely. On the twentieth day the superficial sutures were removed.

The highest point reached by the temperature during the progress of the case was 100.75° and this only on one occasion on the second day at 6.40 P. M., but fell again at 10.20 P. M. to 99.25°.

It was necessary only to pass the catheter twice, viz., on the first and ninth days after operation.

There was never at any time evidence of peritonitis, and the only suspicion of septic infection was in the relaxed and sweaty condition of the skin observed for the first time on the seventh day. It was this symptom which was taken as an indication for washing out the track of the drainage-tube.

The patient was in a condition to get up at the end of the third week, but as I was to be absent from the city for a week she was detained in bed until the end of the fourth week, for fear that there might be some imprudence unless she was carefully watched.

Remarks. I am induced to report this case because of the interest which is at the present time manifested in operations for the removal of tumors connected with the uterus; whether these operations have for their object the ablation of the tumor alone, or this together with the uterus itself, or the uterine appendages, with the hope of bringing about a reduction in the size of the tumor.

The case is interesting for the reason that during the course of the after-treatment the patient never at any time presented symptoms of an alarming nature, either from shock, hemorrhage, peritonitis, or septic infection. It is also a success scored for the intraperitoneal method of treating the stump, although the uterus itself was involved in the ligature. One of the most frequent causes of failure in operations of this nature is hemorrhage from the stump after it has been dropped into the abdominal cavity. This hemorrhage often exists to a small extent from the wound made by the needle in passing the ligature through the stump unobserved before it is dropped and becomes free in the abdominal cavity, partly from the more active circulation after reaction, and partly from the shrinking of the stump itself.

In this connection I would call attention to the method of applying the ligature to the stump employed in this case. After ligating the stump in halves, the ligature was made to encircle the whole stump before it was secured. Even with this precaution hemorrhage continued from the track of the needle employed in passing the ligature. The important point in restraining this hemorrhage was the manner in which the final ligature was applied. The difficulty encountered was to retain this ligature in place and overcome its tendency to slip from the uterus. This could not have been accomplished except by the taking of superficial stitches in the tissue of the uterus.

The final success of the case was due to absolute cleanliness and drainage.

THE ANTRUM OF HIGHMORE, AND SOME OF ITS DISEASES.

By D. H. GOODWILLIE, M.D.,
of New York.

The antrum is a large cavity in the body of the maxillary bone. Above is the floor of the orbit, internally the nasal wall, below the alveolar process. It varies in size and capacity (one to eight ounces), and is larger in the male than the female; it diminishes in old age and after the loss of the teeth. The two antra may be unsymmetrical in size and shape, and sometimes extend into the malar bone, forming a second cavity. It is lined by mucous membrane, and communicates with the nasal cavity in the middle meatus by an opening that varies in size.

If the sinus is large, the second bicuspid and first and second molars may be in close relation to the floor. The roots of the first molar often pierce through the bony floor, and are only covered by the mucous lining of the antrum. The posterior and middle dental nerve courses in the posterior and anterior walls. Disease seldom originates in this sinus, but it is often invaded by disease from without.

Suppuration in the antrum, in the great majority of cases, is the result of suppurative pulpitis, most commonly from the first molar. Caries of the tooth sets up suppurative pulpitis, and the discharge passes through the apices of the roots into the antrum. If the trouble is from the other adjacent teeth, the pulpitis will result in a maxillary abscess, which may then extend into the antrum.

In struma, syphilis, and mercurial poisoning the inferior and middle turbinated bones become necrosed with the antral wall. Trouble in this sinus is sometimes the result of traumatic causes.

Septicæmia is one of the dangers in pent-up pus in the antrum—indeed, is more or less present in nearly all cases, particularly so if there is also a maxillary abscess.

Symptoms of antral abscess are at first a dull aching pain, and as the disease advances infra- and supra-orbital neuralgia, throbbing pain, with redness, swelling, and fluctuation, with rigors and fever. As the pus accumulates, the nasal wall—the weaker one, is quite apt to be forced toward the septum, often producing complete stenosis of the nostril, with, possibly, a discharge of pus. If there is much continued pressure, the stronger wall shows signs of distention, with swelling of the cheek, or the palate is forced downwards. Occasionally the orbital wall will be forced upwards, producing exophthalmus.

Treatment consists in the evacuation of the pus by the extraction of the decayed teeth, and through the socket of the first molar as the most direct course to the floor of the antrum by means of a trephine. This is most efficiently done by the surgical engine. The opening should be one-fourth of an inch in diameter to give free vent to the discharge. This should not be allowed to close until all discharge ceases.

If the case is of long standing, an opening should also be made from the inferior meatus through the nasal wall into the antrum. The sinus is to be kept clean by thymolized water, or bichloride of mercury (1 in 1000) and water. Boric acid or iodoform and camphor powder is to be blown in by means of an insufflator.

If the antrum trouble is the result of constitutional disease, appropriate remedies are to be used in connection with the local treatment.

Catarrh of the antrum is a disease in its earlier stage too little recognized. It coexists with catarrh of the nasal cavity, and is often the primary cause. The opening from the nasal cavity becomes enlarged, and the fetid catarrhal secretion passes into the nasal cavity. This is one source of the trouble called ozæna. There may also be necrosis of the inferior turbinated bone.

The treatment in such cases is to make a free opening from the inferior meatus into the antrum, all necrosis to be removed if any exists. It is to be kept thoroughly cleansed and the powders blown in.

Hydrops antri is a disease characterized by a gradual painless distention of the walls of the antrum, probably by the changes constantly going on in the pent-up secretion. This fluid is clear or yellowish, frequently containing flakes of cholesterine, and is supposed to be the contents of cystic growths within the antrum.

Treatment consists in trephining, cleansing, and use of the powders.

The antrum is often invaded by nasal tumors, which occasionally pass through the antrum and emerge externally into the cheek.

Malignant disease occasionally has its seat here.

Foreign bodies, such as teeth, are found in the antrum and sometimes are in malposition, or by some accident are forced into the sinus.

Lacerations and fractures of the alveolus, by extracting the molars, are frequent causes of antrum trouble.

CASE I. *Suppurative disease of the antrum of Highmore, with dislocation of the cartilaginous nasal septum of twelve years' standing.*—Dr. D. M., of Ontario, Canada, consulted me in November, 1879, and gave the following history: In 1865, had pain in his second left superior molar tooth, and an unsuccessful attempt was made to have it extracted. This probably resulted in rupturing the vessels of the dental pulp, as the doctor says the tooth was started from its socket and then pushed back again. Some time after, from intense pain and swelling of the face, a second attempt was made to extract the tooth. This was not entirely successful, as a root was left in the jaw. From this time the discharge began, and continued until I saw him, more than twelve years after.

He presented the following condition: first and second molars gone from the left superior jaw. Above the alveolus at the position of the second molar, was a fistulous opening, made by a trephine some years ago into the antrum. In this opening he wore a hard-rubber drain-tube, but as it was small in calibre and too high up in order to drain the discharge from the antrum, it was of very little use. It also excited granulations in the cavity. A gelatinous polypus was found in the left nostril, growing from the middle turbinated bone.

This hung by a pedicle over an opening made by necrosis of the inferior turbinated bone and the nasal walls of the antrum.

From the blowing of the left nostril by closing the right with the thumb, to free it from the constant discharge, the lower end of the cartilaginous nasal septum was dislocated and turned into the left nostril, preventing respiration, except when forced. In the pharynx, a muco-purulent track was to be seen on the left of the vertebral ridge, caused by the discharge passing down from the posterior nares. This produced a good deal of expectoration. This trouble continuing for so long a time had very much affected his general health, and prevented him from attending to all his professional duties. On the doctor's first visit in November, 1879, I only removed

the polypus, as it was necessary for him to return immediately home to meet some professional engagements.

In April, 1880, he returned and under an anæsthetic I made first an operation on the dislocated nasal septum. An incision being made through the soft parts, I amputated the protruding cartilage of the septum. The soft parts were brought together and held by small silk sutures; this healed by first intention, and in a weeks' time it would be difficult to tell where the incision had been made. The next part of the operation was the trephining through the alveolar process at the position of the first molar, directly into the bottom of the antrum, by means of a large bone-cutting drill driven by the surgical engine. This opening gave exit to a fetid discharge pent up in the cavity of the antrum. The last part of this operation was the removal, by means of the revolving bone-cutters, of the necrosed turbinated bone and the naso-antral wall, through the anterior nares. This made an opening from the nose into the antrum, extending from the floor of the inferior meatus to the middle turbinated bone and antero-posteriorly about an inch. There was considerable hemorrhage, which was easily controlled.

Through these openings the antrum was freely washed out with thymolized water, and medication applied, which consisted in blowing into the antrum the iodoform and camphor powder by means of the insufflator. There were present at this operation Drs. Farnham, Carey, Warden, and Bucklin of New York; Marvin, of Brooklyn; and Braden, of Michigan. Twelve months after the operation the mucopurulent discharge ceased, and he is now in robust health. The respiration through the occluded nostril is quite free. The opening from the mouth into the antrum has now closed up. A permanent opening will remain in the naso-antral wall where the necrosis was removed.

CASE II. *Suppurative disease with exophthalmus.*—In July, 1881, Dr. Carey referred to me Mrs. A. C., who had extensive swelling of the left cheek, with exophthalmus. Nostril on that side closed. She suffered great pain; teeth on that side much decayed. Treatment consisted in removing the decayed teeth and trephining through the alveolus into the antrum. The antrum was also trephined through the naso-antral wall in the line of the inferior meatus. The pent-up fetid pus flowed freely from the antrum through these openings and gave her great relief from pain. The sinus was kept thoroughly cleansed and the swelling and exophthalmus gradually passed away.

CASE III. *Tooth found in the antrum.*—I was consulted in 1869 by Mrs. S A., of Philadelphia, Pa., who gave the following history: Having pain on the right side of her mouth, she had some decayad teeth extracted. Severe pain soon returned and had continued some months before I saw her. There was great swelling of the jaw and face; palate forced downwards; distention of the naso-antral wall, with some discharge from the nostril and alveolar process. Administered an anæsthetic and trephined through the track of the fistulous opening in the alveolar process, which was necrosed into the antrum. On entering the antrum, the trephine struck against some hard foreign body. After the opening had been enlarged, a tooth was found in the antrum and removed with all the necrosed bone. This operation removed the entire floor of the antrum. As all the periosteum was preserved, the case recovered rapidly and left very little deformity.

The probable explanation of the presence of this tooth in the antrum is as follows, viz.: A suppurative pulpitis was followed by a maxillary abscess around the roots of the molar tooth; the pus finding its way into the antrum produced inflammation and suppuration, resulting in alveolar necrosis, and when the teeth were extracted this one was forced into the antrum in attempting to apply the forceps.

CASE IV. *A tooth developed in the antrum.*—Isaac C., aged 18 years, was brought to me by Dr. Carr. The young man had been suffering pain in his right superior maxilla which commenced six years before and had steadily increased up to the time I saw him. It was thought at first to be an alveolar abscess and the doctor lanced it, but with only temporary relief to his pain. There was found on examination the following condition: There was a swelling commencing at the canine fossa and extending back to the hamular process. Stenosis of the right nostril with nasopharyngeal catarrh. All the teeth on that side of the mouth were developed and in normal position with the exception of the canine. From the absence of the tooth and the nature of the discharge that occasionally came away, together with the other symptoms, I was of the opinion that it was a dentigerous cyst.

Treatment consisted in placing the patient under an anæsthetic, and pulling well back the cheek by means of a retractor, and in making an incision from the canine fossa backwards one and one-half inches, and three-quarters of an inch above the border of the gum. The periosteum was now denuded from the bone, and by means of the revolving bone knives the cyst was opened into, and quite a quantity of an amber-colored liquid escaped. On a careful examination of the interior of the cyst, the canine tooth was found fully developed and lying in the bone of the floor of the antrum, the root presenting anteriorly. The soft parts that were denuded were united by suture, the anterior corner being left for the purpose of cleansing the antrum and cyst. A reproduction of bone took place from denuded periosteum, and six months after nothing remained to show that any operation had been performed. The stenosis of the nostril was relieved by extirpating the inferior turbinated bone by means of the revolving scissors and surgical engine, in order to make a free passage.

CASE V. *Abscess of the antrum of ten years' standing.*—W. N., aged 51 years, born in England, had tooth disease commencing ten years before, from which time he has had neuralgia with nasal catarrh. After treatment by his family physician he was referred to a specialist, by whom he was treated for nasopharyngeal catarrh, but he steadily grew worse and gave up treatment. Suffering from pain and the discharge, he was unable to sleep at night in bed, but reclined in a chair.

When I first saw him he was suffering intense

infra- and supra-orbital neuralgia, with rigors and fever. Slight redness and swelling of the right cheek. Muco-purulent discharge from the right nostril. All the molars and the second bicuspid were gone. The bicuspid had been removed not many days before.

Treatment consisted in trephining through the alveolus into the antrum and in enlarging the opening in the naso-antral wall into the inferior meatus. The discharge was very fetid. The antrum was kept thoroughly washed out and boracic acid blown into the antrum and into the nostril. The passages were kept open and the treatment carried on for several months, and he entirely recovered.

MEDICAL PROGRESS.

Subcutanfous Injections for Cholera.—Samuel holds that cholera is a process which causes death by an incoercible transudation. The local treatment (anti-parasitic or antidiarrhœal) cannot, on account of the rapid removal of the remedies or their extreme dissolution, give any good result. General treatment in this way is also doubtful. It is only necessary to maintain the circulation for twenty-four or thirty-six hours, and he recommends multiple injections under the skin, in different regions of the body, of solutions of six parts (by weight) of common salt and one of bicarbonate of soda to one thousand of distilled water. These injections should be kept up during the whole period of asphyxia.

At the meeting of the Verein für innere Medicin of Berlin, on July 14, Dr. Kronecker said that he considered the intraorganic injection of common salt as the really effective method of combating cholera. The quantity to be used is not a matter of indifference, and experiments on animals do not give the needed data; one animal will support well a quantity which would be fatal to another. For man, from the results of hypodermatic and nasal injections, it seems that a solution of seventy-three parts of salt to one hundred of water (by weight) is the quantity best supported.

Should the injections be intra-arterial, intravenous, or simply subcutaneous? Kronecker has always injected the solution into the veins; this is the surest method. But care should be taken that no more than 20 c.cm. (3v) enter the circulation per second; for this purpose a graduated flask should be used.

The Society appointed a commission of seven members to investigate the subject.—*Berliner klin. Wochenschr.*, July 28, 1884, and *Wiener med. Presse*, July 27, 1884.

The Consequences of Extirpation of the Thyroid Gland.—J. Wagner has just completed a series of experiments, on this subject, made on dogs and cats. After extirpating the thyroid gland, he studied the nervous disturbances which followed. The most of the cats operated upon were only a few weeks old. After complete extirpation, trembling of the extremities and fibrillary muscular spasms occurred, which, though scarcely perceptible at the beginning, became more pronounced later, and interfered with the locomotion of the animal. Sometimes the muscular tremors amounted to clonic cramps, and they, in turn, were succeeded by tetanic convulsions. The locomotion was stiff and sprawling. The respiration was dyspnœic during the cramps. The sensibility was very much diminished, and perhaps there was also some paræsthesia. In one case, there was clearly a marked increase in the mechanical and electrical nervous irritability. In every case, death occurred between the second and fourth day, and there was a tendency in the animals to run backwards. Nothing noteworthy was found at the post-mortem examinations.—*Centralbl. f. d. med. Wissensch.*, July 26, 1884.

The Microbe of Syphilis.—At the meeting of the Société de Biologie, on July 12th, MM. Marcus and Tornéry communicated the results of their researches on the microbe of syphilis. They conclude that:

1. An easily colored coccus, occurring in colonies, is found in syphilitic products, and in cultures from them.

2. These cocci are easily cultivated in an infusion of peptonized beef, to which gelatine and an alkali have been added.

3. They are found in indurated chancres, and in the lymphatic ganglia.—*Gaz. Hebdom.*, July 25, 1884.

Extirpation of the Carcinomatous Uterus.—A. N. Solowjeff reports ten cases in which he removed the carcinomatous uterus, by the vaginal method, in 1881–83. The results were as follows: Seven recovered, and are living now, and three are dead. Of the recoveries two (one twenty and one eighteen months after the operation) have no return of the carcinoma; in one case recovery seems to be complete; in two no anomalous conditions are found near the cicatrix; in one there are nodules in the cicatrix; one lost sight of. Of the three fatal cases the disease returned in the broad ligaments in one; a portion of the growth was left in the broad ligament in another; and the third died of sepiticæmia.—*Centralbl. für Chirurgie*, August 2, 1884.

The Infectiousness of the Air in Rooms Occupied by Phthisical Persons.—L. von Wehde has recently made experiments on this subject by collecting the dust from the air in rooms occupied by phthisical persons. After one, one and a half, and two days the glycerine appeared clouded, to the naked eye. Water, into which dust, collected on a dry plate, was placed, also became clouded. Fifteen animals were then inoculated with the soiled fluids. The inoculations succeeded in eleven cases; the other four "died soon after the inoculation of other causes (?)"—*Centralbl. f. d. med. Wissensch.*, August 2, 1884.

Teratoma of the Pituitary Gland.—H. Beck reports, in the *Prager Ztschr. für Heilkunde*, 1883, Bd. iv. Hft. 5 *u.* 6, his examination of a tumor of the pituitary gland, which Chiari found in a woman seventy-four years of age. It had caused trouble of vision, by producing a flattening of the optic chiasm. The tumor was the size of a walnut, and contained cysts with gelatinous contents, teeth, and bones; the cavity was lined with ciliated epithelium.—*Centralbl. f. d. med Wissensch.*, August 2, 1884.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, SEPTEMBER 20, 1884.

INTRAVENOUS INJECTIONS.

IT must be reluctantly admitted that the operation of transfusion of blood, philosophical as it seems, and powerfully as it appeals to the earnest desire of every true physician, that he may do some great thing toward saving a valued human life as occasion requires, has not fulfilled its early promise, and has consequently fallen out of favor with surgeons here as elsewhere. Among the causes of this decadence in popularity, may be mentioned the great danger that, even in so-called defibrinated blood, minute masses of fibrin, or aggregations of red corpuscles, may act as emboli, and quickly cause grave or fatal disorders in the brain, lungs, and liver. Other objections are found in the difficulty of procuring healthy blood in sufficient quantity, at the moment when it is most needed, and to a less degree the chances of conveying disease into the body of the recipient. Within the past few months, however, so many reports of success abroad, by the intravenous injection of a solution of common salt and carbonate of sodium, representing the salines of the blood-plasma, have reached us, that it seems almost a duty for us to undertake new experiments in this country, in order to test the practical value of so plausible a method for obviating the tendency to death in cases of profuse hemorrhage.

In a remarkable instance reported among others by PROF. MIKULICZ, of Cracow, a young man, who had lost so much blood from a wound in the brachial artery that his pulse was barely perceptible and was beating at the rate of about one hundred and thirty per minute, was operated on by the gradual injection of twenty ounces (600 c. c.) of the compound salt solution, with immediate and obvious benefit and ultimate cure. Dr. Fux, of Laibach, records the case of another youth, who, in consequence of repeated hemorrhages from a neglected wound in the hand, had become profoundly anæmic, but was satisfactorily prepared for successful operation upon the injured member by an intravenous injection of eight and a half ounces (250 c. c.) of salt solution. Dr. Fux, as a result of his experience, fully endorses the assertion of Szuman that the injection of salt solution in acute general anæmia is an enormous advance in therapeutics, and deserves to be held in very high esteem as a surgical resource in threatened death from hemorrhage.

The solution employed by Mikulicz was composed of one part of carbonate of sodium, six parts of common salt, and one thousand parts of distilled or twice-boiled water, warmed in a bottle of the temperature of 104° F. (40° Cent.), and injected into the median basilic vein, by the mere weight of a column of the fluid twenty inches in height, contained in a funnel and rubber tube attached to the canula, which had been inserted into the vein. Great care was taken to insure complete antisepsis by transmitting a five per cent. carbolic acid solution, to wash out the apparatus previously, and the amount of salt solution slowly injected varied from seventeen to fifty ounces (500 to 1500 c. c.).

It seems to be proved by experiments upon animals, and also by clinical facts already in our possession, that the mortality in most cases of excessive loss of blood does not occur from scarcity of red corpuscles chiefly, but in consequence of the total bulk of the vital fluid being so far diminished that the vascular system, and especially the cerebral and coronary arteries, are not kept full enough to enable the organs concerned duly to perform their functions. That it is not the mere diminution of the solid constituents of the blood which is the essentially fatal condition, is shown by the facts that in profound anæmia the number of red corpuscles may fall to 500,000 per cubic millimetre, or one-tenth their normal amount, whilst the albumen and fibrin may also be very much reduced, in hypalbuminosis and hypinosis without destroying life.

Hence, if the favorable results already reported are confirmed by other observations under varying conditions, we believe that the operation of "Koch-salzinfusion" will speedily assume an important place, as a remedial measure against death from excessive loss of blood. Perhaps, indeed, it may ultimately take rank among the four or five surgical procedures, such as that of tracheotomy, and the operation for relieving strangulated hernia, which every physician should keep himself both *mentally* and *instrumentally prepared*, to perform at a moment's notice. It is ap-

plicable not only in cases of external wounds, but also in internal hemorrhage from gastric or intestinal ulceration, and in the uterine hemorrhage of abortion, or of placenta prævia, or from inertia after parturition is accomplished.

VAGINAL EXTIRPATION OF THE UTERUS.

THE subject of kolpohysterectomy, or removal of the uterus by the vagina, is very fully discussed by DEMONS, of Bordeaux, in the *Révue de Chirurgie* of August. He holds that while cancer of the uterus offers by far the most frequent indication for the operation, yet it may be given by myomata situated at the fundus of the uterus; when a myoma is of medium size and submucous, situated as mentioned, the patient may die from hemorrhage, and therefore, other means failing to stop the blood-flow, it is better to remove the uterus by the vaginal method. An indication for partial removal of the uterus is given by an irreducible inversion of the organ.

In determining the propriety of the operation in a case of cancer of the uterus, a most careful examination must be made, and for this it is necessary in many cases thoroughly to anæsthetize the patient,—at least the abdominal muscles must be completely relaxed. The examination is made by abdominal palpation, by vaginal and rectal touch. In a case suitable for the operation there should be no enlargement of the lumbar glands, no tumefaction of the broad ligaments, the vaginal cul-de-sacs should be free from swelling, of normal elasticity, and the uterus should be quite movable. This mobility is best tested by catching the cervix with a tenaculum, and drawing the organ toward the vulva, at the same time, as advised by Schröder, that rectal and vaginal touch are made, so that the broad ligaments can thus be included between the fingers, and their freedom from disease be ascertained.

The operation is to be rejected in case the disease involves simply the intravaginal cervix, for then removal of this only is advisable Even if the disease has extended to the internal os, supravaginal amputation of the cervix may be done, but total extirpation is necessary if the mucous membrane of the body is involved as well as that of the neck.

In the operation the patient is completely anæsthetized, and by means of continuous traction with Museux's forceps fastened to the cervix, the latter is drawn to the vulval orifice; then a circular incision is made around the cervix, when the finger is used to detach the uterus, keeping it close to this organ; the detachment is made but slightly behind and at the sides, but carried in front to the anterior peritoneal cul-de-sac; occasionally a probe-pointed bistoury may be necessary to divide very resisting portions of connective tissue. The peritoneum is opened, if possible, with the finger, if too resisting with the bistoury, and then two fingers are passed over the fundus of the uterus so as to draw it into the vagina; in some cases this eversion of the uterus cannot be effected by the fingers, and then a strong hook must be used for the purpose.

The next, and the most difficult step of the operation, is ligating the broad ligaments. For this a curved needle—Cooper's is advised—is required, and Demons uses catgut ligatures, No. 1 for the upper, and No. 2 or 3 for the two lower. After introducing the three ligatures on one side, and tying them, the ligament is divided either with a probe-pointed bistoury, or blunt-pointed scissors; next the ligatures are applied to the broad ligament of the other side, and it is then similarly divided; finally, the bistoury is used to cut the peritoneum posteriorly, and the uterus falls out. Demons states that it is unnecessary to remove the ovaries, as the patients do not have any acute pain at menstrual periods, and there is no intra-abdominal hemorrhage.

The statistics of the operation given by Sänger, in 1883, are quoted, showing that in 143 extirpations of the uterus—133 for cancer, 6 for prolapse, and 4 for myomata—72 per cent. recovered, while 28 per cent. died. While immediate recovery is then the rule even in cases of kolpohysterectomy for cancer, yet in the majority the disease returns in four or five months, and the patient dies in a year or fourteen months after the operation. Demons, while recognizing the difficulties of the operation, states that he has less fear in the removal of a mobile uterus, than in that of a nasopharyngeal polypus with multiple prolongations, or of a suffocating goitre.

LITHOLAPAXY.

WE cannot at this moment recall a single surgical operation which has so rapidly become an accepted procedure as lithotrity at one sitting. From the very date that PROFESSOR BIGELOW published in *The American Journal of the Medical Sciences*, six years ago, an account of his new method of dealing with urinary calculi, surgeons of all parts of the world have demonstrated the merit of his great achievement, and it is interesting to note that, in the hands of those having the greatest experience in the treatment of calculous subjects, litholapaxy has as effectually displaced ordinary crushing as the latter procedure has displaced lithotomy.

That the latter statement is strictly true is shown by a comparison of the three procedures in adults, as practised by the same surgeon. From two lectures delivered at the Royal College of Surgeons, and published in the *British Medical Journal* for July 12 and 19 of this year, we find that SIR HENRY THOMPSON has had 782 cases of operation for stone in adult

males. Among his first 200 cases, 48, or 1 in nearly every 4, were subjected to lithotomy. In his next 371 cases, 19, or 1 in every 19½, were cut; while in his last 211 operations, 15, or 1 in every 14, were lithotomies. VON DITTEL, as reported in the *Wiener med. Wochenschrift*, Nos. 3 to 11, 1884, lithotomized 46 of his first 100 patients, 32 of his second 100, and only 13 of his third 108, the ratio of those cut having been reduced from 1 in 2.17 to 1 in 7.69. In the crushing operations litholapaxy rapidly displaced ordinary lithotrity, and lithotomy was reserved, as a rule, for encysted calculi and stones of unusually large size.

That Bigelow's operation is safer than other operations for urinary calculi in adult males is proved by some other facts set forth in the lectures of Sir Henry Thompson. Thus, of 110 lithotomies, 39 were fatal, the mortality being 35.5 per cent., which is simply enormous. Of 478 ordinary lithotrities, 33 died, the mortality being 6.9 per cent.; while of 194 litholapaxies, 10, or 5.15 per cent., were fatal. These results clearly show that litholapaxy must supersede not only the old operation of crushing, but also cutting operations except in cases in which the stone is of exceptional size or hardness.

The results of rapid lithotrity, as performed by different operators, indicate a mortality of about 5.4 per cent. This death-rate does not appear to have been materially lessened by the experience of those who have had the most frequent opportunities to do the operation. Thus, Freyer's 76 cases show 3 deaths, or a mortality of 4 per cent. Von Dittel's 80 cases afford 5 deaths, or a mortality of 6.25 per cent., and Sir Henry Thompson's 194 operations have yielded 10 deaths, or a mortality of 5.15 per cent. The entire number, or 350 cases, show 18 deaths, or a mortality of 5.1 per cent., a result which may be improved upon, but with which we should have every reason to be satisfied.

THE ANATOMY OF THE LABIA MINORA.

IT has hitherto been generally taught in all works upon anatomy and obstetrics that the nymphæ are "folds of mucous membrane." But the recent researches of DR. HENRI CARRARD (*Zeitschrift für Geburtshülfe und Gynäcologie*, Band x. Heft 1) must lead to a rejection of this view. He states that, from his microscopic examination of normal nymphæ, their covering has histologically, in spite of its moist mucous-membrane-like appearance, the character of skin. Its superficial layers are formed of numerous non-nucleated, flat cells; it contains many well-developed papillæ and an abundant supply of sebaceous, but no mucous glands. Further, Carrard has found in the papillæ, as a constant condition of the terminal nerves, Meissner's corpuscles—an occurrence which is a strong argument against the nymphæ being formed of folds of mucous membrane.

Hildebrandt, in the handbook of Pitha and Billroth, has attributed vulval pruritus in many cases to enlarged capillaries in the nymphæ, comparing it to the itching caused by hemorrhoids. The pruritus observed in some cases of pregnancy, or of uterine fibroids, or of ovarian tumors—all conditions, in short, which induce a greater flow of blood to the parts, or hinder its return—may be thus caused. But Carrard has not observed this alleged enlargement of the capillaries of the nymphæ in pruritus, and, therefore, rejects Hildebrandt's explanation; but he did find upon microscopic examination of hypertrophied nymphæ removed from patients who had suffered from violent pruritus, that the enlargement concerned the connective tissue layers, and the nerves therein lying, the latter being three or four times greater than normal.

GANGLIAR DISEASE OF JOINTS.

IN the *British Medical Journal*, for August 30, MR. A. T. NORTON calls attention to a hitherto undescribed destructive disease of joints, which resembles in external appearance, and often in its symptoms, scrofulous disease and rheumatic disease. It is associated with the presence of ganglions in the adjacent tendons, and the ganglions may or may not be connected with the articulation.

Gangliar disease of the joints is essentially a chronic affection, extending frequently over ten to fifteen years, and occurs almost invariably after the thirty-fifth year, elderly persons being most liable to it. It arises spontaneously, the affected joint is not tender to the touch, nor accompanied by much pain, although there is often aching, when the patient refuses to use the limb. With the progress of the disease, the joint becomes useless, the ligaments give way, and, in the case of the wrist, there is a lateral gliding motion, and the hand hangs and cannot be lifted. When the bones ulcerate and suppuration is established, pain and elevation of temperature are superadded.

The disease invariably terminates in ulceration of the bones, preferably those of the carpus and tarsus, which progresses very rapidly until all the separate pieces are affected, and some completely disappear. The synovial membrane is villous or granular, the joint is distended with fluid, and there is always associated gangliar disease of the tendons, the cyst being filled with the usual gelatinous material and melon-seed-like bodies.

The presence of ganglions suffices to differentiate the affection from common ulceration of the cartilages, or from rheumatic disease. In strumous synovitis the swelling is fluid, and not solid to the touch, as in gangliar disease. In diagnosticating from

rheumatism, the enlarged bursæ which occur in that affection must not be confounded with ganglions.

The treatment is not satisfactory, as the disease is progressive. In the early stages, the ganglions and joint may be aspirated, and the limb may be fixed upon a splint, and discutient lotions be applied. When, however, the hand hangs, or the joint glides, amputation is demanded.
